For decades after the first description of medulloblastoma was published by Bail and Cushing in 1925, the prognosis for this highly malignant tumor was extremely poor. Cushing’s development of neurosurgical techniques to remove tumors of the fourth ventricle, coupled with a dramatic decline in surgical morbidity, was critical to the development of effective therapies.[1113] With the introduction of radiation therapy and further refinements in neurosurgical techniques between 1950 and 1970, significant improvements in survivorship were achieved. For the first time patients with standard-risk disease had a 5-year EFS approaching 50%, whereas those with high-risk disease were estimated to have a 5-year EFS of approximately 20%. It was demonstrated that radiation therapy could cure a significant percentage of patients, thus securing its place in the standard approach for these tumors. The craniospinal dose for all patients at that time was 3600 cGy (craniospinal irradiation; CSI), with a posterior fossa boost to an approximate total of 5400 cGy. The promise of EFS was tempered, however, by the poor functioning levels seen in surviving patients.

Based on these outcomes and late effects, treatments were modified on the basis of risk categories. For high-risk patients, chemotherapy was added to full-dose 3600 cGy craniospinal radiotherapy, and the resulting improvement in outcome was easily measured, with 3- and 5-year EFS rates of approximately 60%. By contrast the approach to patients with standard-risk disease was to reduce the dose of craniospinal radiotherapy from 3600 to 2400 cGy to spare neurocognitive function, while maintaining the boost to the posterior fossa of 5400 cGy. A national clinical trial in the United States was undertaken, but as the study progressed, there was concern that the number of recurrences in the 2400-cGy treatment arm was greater than that for the 3600-cGy treatment arm. Consequently the study was terminated early. With further follow-up, however, the survival curves for the two treatment arms began to approach one another, such that no statistical difference in outcome was identified, and the early termination of the trial hindered the determination of the statistical conclusion. The results from these treatment studies suggest that chemotherapy in combination with craniospinal radiation therapy could positively affect outcome. The strategy for standard-risk disease thus became the lower-dose radiation therapy of 2400 cGy CSI with the addition of chemotherapy. In follow-up studies of these combinations, PFS of 86% and 79% at 3 and 5 years, respectively, was achieved for standard-risk patients.[1114] The two approaches for high- and standard-risk disease have now become the basis of most North American treatment trials.

Current Treatment

Management. A high level of clinical suspicion is critical for an early diagnosis of medulloblastoma. Neuroimaging is usually the first step, with CT or MRI scanning of the brain frequently performed in the acute setting. MRI of the brain and spine should be performed as soon as is feasible. In children in whom the diagnosis of medulloblastoma is suspected, an MRI of the spine should be obtained because the incidence of CSF dissemination at diagnosis ranges between 20% and 30%.[1077] Corticosteroids are usually used to control increased ICP. A lumbar

Box 57-3 Modified Chang Staging System in Medulloblastoma

Stage M0: No evidence of subarachnoid or hematogenous metastases
Stage M1: Microscopic tumor cells found in the cerebrospinal fluid
Stage M2: Gross nodular metastatic seeding in the subarachnoid space or ventricular system distant from the primary site of disease
Stage M3a: Gross nodular seeding in the spine subarachnoid space without evidence of intracranial seeding
Stage M3b: Gross nodular seeding in the spinal subarachnoid space, as well as intracranial seeding
Stage M4: Extraneural metastases

puncture should be deferred until after intracranial hypertension has been relieved by surgery. Because extraneural spread of medulloblastoma is possible, bone marrow aspiration and biopsy should be considered for the complete evaluation of patients with medulloblastoma,[1115] although these procedures are no longer required for participation in cooperative clinical trials. Although the exact incidence of extraneural metastases is evolving, current estimates suggest that such metastases occur in fewer than 5% of patients. Because patients will require general anesthesia for insertion of a central line for the administration of chemotherapy, bone marrow samples and a baseline lumbar sample can be easily obtained with minimal trauma to the child or family. CSF obtained from the ventricular or cisternal fluid is not considered an adequate sample upon which to base staging decisions; thus lumbar sampling is recommended for all patients in whom such sampling is not contraindicated pretherapy.[1116]

At present risk stratification and treatment assignment are based primarily on clinical factors, although this will change with greater reliance on molecular profiling.[1111] Recently histology has been added in the risk assignment of medulloblastoma. The modified Chang criteria[1117] are based on the extent of tumor and the degree of metastasis (Box 57-3). After completion of the staging evaluation (i.e., MRI of the brain and spine, CSF cytology, and bone marrow studies), histology, and degree of resection, patients are stratified to the standard-risk, high-risk, or infant-risk groups. The major determinants of clinical risk categorization are age at diagnosis (younger than 3 years vs. 3 years or older),[1072] metastasis or M stage (M0 versus higher than M0), volume of residual postoperative disease (less than 1.5 cm^3 residual disease vs. greater than 1.5 cm^3 residual disease),[1118] and histology (anaplastic–large cell versus other).[1119] Although these criteria are widely used in the staging of medulloblastoma, the role of complete resection versus less than 1.5 cm^3 residual disease, the age of the patient, and the significance of anaplastic histology are still in question, and entry criteria may vary from those indicated.

Histology has just recently begun to be considered in risk stratification. Most prior published series of patients with medulloblastoma had incorporated patients with anaplasia–large cell medulloblastoma into standard-risk treatment if they met the other criteria for standard risk. The recognition that infants with the desmoplastic variant may do better than infants with the nondesmoplastic variant may provide an opportunity to deescalate therapy in this particular group. Newer protocols are now incorporating these variables. Tolerability of therapy has also recently come to light as more adult programs begin to treat older patients with regimens similar to those that have produced significant advances in pediatric patients. Older patients, including adolescents, do not tolerate therapy as well as younger children or infants, which provides an argument for dose modifications in this group.[1120]

ATRTs of the posterior fossa often resemble medulloblastomas. In prior cooperative group studies, up to 30% of patients with ATRTs were misclassified as having a medulloblastoma. With the use of INI1 immunohistochemical analysis of the tumor sample, rapid differentiation of these two histologies is required because the treatment for ATRT differs from that of medulloblastoma in most large cooperative groups.

Treatment

Surgery. Treatment of medulloblastoma, as well as of other embryonal tumors, is multimodal, consisting of surgery, radiation therapy, and chemotherapy, with current therapies guided primarily by age and stage at diagnosis. The initial goal of surgery is to control raised ICP, if present. Once the safety of the patient is ensured, consideration of tumor resection becomes the next objective. If metastatic tumor is already known to be present, immediate aggressive surgery within the posterior fossa will not reduce the need for more intensive radiation therapy and chemotherapy. Rather the goal of surgical resection should be to achieve maximal tumor volume reduction without significant damage to adjacent areas. In balance it is more important for the neurosurgeon to preserve function rather than to maximize resection. Given the excellent prognosis for patients with medulloblastoma, even with metastatic disease, damage to the brain in a high percentage of patients means a high percentage of survivors with permanent neurologic damage.[1121] A third ventriculostomy (preferred) or VP shunt should be deferred prior to initial surgery but may be necessary if sufficient resection to reopen CSF flow is not achieved.

A number of surgical approaches are possible to optimize resection of posterior fossa and cerebellar tumors. Most fourth ventricular lesions will require interruption of the cerebellar vermis, although resections through the vermis using horizontal or vertical incisions have both been associated with posterior fossa syndrome. Even attempts at going under rather than through the vermis have been associated with this morbidity. The brainstem must also be protected while removing medulloblastomas within the fourth ventricle. Because these tumors can invade the brainstem, intraoperative decisions regarding the aggressiveness of resection must be made. Similarly resection must protect the nearby cranial nerves. New neurosurgical techniques are now available that allow for greater guidance in resection and in physiologic monitoring so that damage to important anatomic structures can be avoided. The use of intraoperative MRIs has improved the neurosurgeon's ability to ensure adequate yet safe resection.[1122,1123]

Potential complications of surgery in this location, regardless of tumor type, include cerebellar mutism (also called posterior fossa syndrome)[1124] and aseptic meningitis. The posterior fossa syndrome, or cerebellar mutism, occurs in approximately 10% to 20% of cases, although it is being reported in an increasing percentage of patients as more attention is given to the quality of survivorship. The characteristics are reduced speech output or mutism, personality changes, hypotonia, ataxia, and reduced oral intake. Symptoms typically appear 1 or 2 days after surgery, may range between mild to severe, and may last from days to months with varying degrees of recovery.[1125]

Radiation Therapy. Radiotherapy has become an important modality in the long-term outcome of patients with medulloblastoma. During the past 20 years, a great deal of effort has been focused on the reduction of craniospinal doses as a result of significant long-term neurocognitive damage, as well as secondary tumor risk and stroke. Radiotherapy is currently risk adapted, and additional modifications to dose and volume continue.[1126] For standard-risk patients, 5400 to 5580 cGy are administered to the tumor bed. This volume continues to evolve, from inclusion of the entire posterior fossa, even when the tumor is small and focal, to more limited fields that encompass only structures in contact with the tumor and a small margin. Previous standard-radiation therapy included craniospinal doses of 3600 cGy. A national clinical trial evaluating standard-risk patients with a craniospinal dose of 2400 cGy demonstrated equal efficacy to historic reports, although this study did not randomize between the two CSI doses; 2400 cGy has been accepted as the new standard for this patient population.[1127] An important conclusion from this study was the poor outcome of patients with high-risk disease treated with lower dose craniospinal radiotherapy, reinforcing the importance of proper staging and radiation planning for all patients. A COG clinical trial for patients with standard-risk medulloblastoma is ongoing; this trial randomizes children younger than 8 years to receive either 2400 or 1800 cGy CSI and randomizes all children to receive either a full posterior fossa boost or an involved field boost. This trial will help define the dose and field of radiation therapy required for this population.

For patients with high-risk disease that is caused either by the presence of bulk unresectable disease within the posterior fossa or by the presence of metastatic disease, treatment remains 3600 cGy to the craniospinal axis and a focal dose to the involved posterior fossa of 5400 to 5940 cGy. Although this dose to the entire brain and spine increases the morbidity of therapy, it is an important component of effective treatment, as noted in the previously described randomized trial for standard-risk patients who, on central review, were found to have high-risk disease. A number of cooperative group trials are currently evaluating drugs combined with radiotherapy (radiation sensitizers) to augment the activity of radiation therapy in children with high-risk medulloblastoma.

Infants with medulloblastoma (and other CNS PNETs) continue to pose the greatest therapeutic dilemma. Even in the presence of standard-risk disease, the contraindication for craniospinal radiation therapy limits the treatment options for this group and their long-term prognoses. The omission of craniospinal radiotherapy has required the acceptance of a lower cure rate but a much higher functionality for those who do survive.[1128] The use of treatment protocols that rely only on surgery and chemotherapy demonstrate a relatively poor outcome for this group in all but a select group (e.g., those with nodular desmoplastic medulloblastoma[1097]), again supporting the importance of radiation therapy for the treatment of medulloblastoma. Because many relapses occur locally, many centers have tested focal radiotherapy to the posterior fossa, forgoing the craniospinal component of therapy.[727,1129] This approach attempts to improve local control to the cerebellum, which is thought to be an area less important for neurocognitive development than the cortex. However in a recently completed COG study (trial P9934) that pilot-tested focal radiation therapy to the posterior fossa, it was noted that many recurrences occurred in sites that were outside the radiation field.[1130]

Hyperfractionation of radiotherapy—that is, twice-daily dosing of radiation therapy—has not demonstrated significant improvement in outcome,[1131] although one pilot trial has reported such an improvement.[1132] By contrast a significant delay in the completion of the radiation therapy appears to negatively affect survival.[1133,1134] Proton radiation therapy is increasingly used for children with medulloblastoma. Although its efficacy is similar to that of conventional photon radiotherapy, the absence of an exit dose can reduce radiation exposure to areas uninvolved with tumor. The limited number of proton beam facilities, however, restricts the wider application of this technique. Other more readily available radiation therapy options include IMRT. In particular, tighter margins within the posterior fossa and better 3D conformal planning with IMRT-based techniques can help avoid the auditory apparatus and thus long-term hearing impairment.

The potential use of chemotherapy before delivery of craniospinal radiotherapy has been pilot tested[1134,1135] and has been shown to be associated with inferior EFS and OS.[1135] A national clinical trial with randomization between standard-dose radiation therapy (3600 cGy) and reduced-dose (2340 cGy) CSI in patients with low-stage (M0) disease who were not receiving adjuvant chemotherapy resulted in an increased rate of recurrence outside of the posterior fossa.[1136] However it should be noted that no statistically significant difference was found between the two groups at 6 to 7 years after treatment.

Chemotherapy. The chemosensitivity of medulloblastoma and the benefits of adjuvant chemotherapy in treatment regimens have been demonstrated by a number of studies.[1137-1139] During the past 20 years studies have shown a nearly 20% to 30% improvement in EFS and OS by using chemotherapy during and/or after radiation therapy. Most regimens have included vincristine, cisplatin, etoposide, and an alkylator (cyclophosphamide or CCNU). Although platinum-containing regimens are considered important components of the treatment of medulloblastoma, the ultimate cumulative dose required for optimal activity while minimizing renal and audiologic impairment remains to be defined.[1140] Chemotherapy is currently a standard adjuvant therapy in children. Similarly infant studies with chemotherapy alone have shown the importance of chemotherapy as an effective strategy for patients with medulloblastoma. For most of these infant studies the removal of CSI has had a negative effect on survival, although a significant proportion of survivors can achieve cure.[1097] Recently methotrexate has been added into multiagent chemotherapy for medulloblastomas and other PNETs with excellent tumor response. In one phase II study consisting of four cycles of carboplatin, etoposide, and methotrexate, CR and partial response (PR) rates of 71% and 81% were achieved in patients younger than 3 years and older than 3 years, respectively.[1141]

The concurrent use of craniospinal radiation therapy and multiagent chemotherapy for medulloblastoma can result in significant impairment of nutrition during therapy for these patients.[1142] Patients who present with persistent vomiting likely initiate therapy in a negative nutritional state. A large proportion of patients will require nutritional support through a nasogastric tube or gastric tube. Constant surveillance of nutrition is important because this issue is often dismissed early and is only recognized when severe weight loss has occurred.

Impairment in hearing function continues to be a major concern in survivors of medulloblastoma. The overlap between posterior fossa radiation therapy and the use of ototoxic drugs such as cisplatin has resulted in significant toxicity for this patient population. Conformal radiation planning with tighter margins, the use of IMRT, and the use of proton beam radiation therapy can all significantly reduce the damage to the auditory apparatus. Recent medulloblastoma treatment protocols have also reduced the cumulative doses of cisplatin. The use of amifostine continues to be controversial, with some studies showing efficacy at protecting hearing and other studies not showing efficacy.[1143,1144] Concerns about protecting the tumor from the chemotherapy remain, and only a well-controlled randomized trial will resolve this question.

STANDARD-RISK DISEASE. The components of combination chemotherapy used during and after CSI continue to evolve. A large national clinical trial involving 2400 cGy CSI with a boost to 5400 cGy to the posterior fossa and randomizing between vincristine, cisplatin, and either CCNU or cyclophosphamide (COG trial A9961) demonstrated that both treatment arms have approximately similar activity. The OS for both groups was approximately 90%, with only a slight difference in EFS between the two chemotherapy regimens (85% for patients who received CCNU vs. 83% for those who received cyclophosphamide).[1035] The emphasis in the ongoing clinical study has been to reduce the CSI dose further in a randomized fashion for children younger than 8 years (i.e., those most at risk for the severe neurocognitive impact of radiation therapy) while combining the CCNU and cyclophosphamide agents to reduce the total exposure to each. The safety of 1800 cGy craniospinal radiotherapy was pilot tested in 10 patients with standard-risk medulloblastoma, and in this small cohort, the survival outcome appeared equally effective to that for 2400-cGy therapy and with less neurocognitive impairment.[1145] Radiation- and chemotherapy-adapted approaches are especially important for younger patients given the significant dose-dependent neurocognitive impact of radiation therapy in this population.[1146] A large European cooperative group trial of standard versus hyperfractionated radiation therapy showed no significant outcome difference between these two approaches and has led to the adoption of daily fractionated radiation therapy as the standard for children with medulloblastoma.[1147]

HIGH-RISK DISEASE. Treatment strategies for this population have focused on the addition of new agents, including radiosensitizing agents and novel biologic inhibitors, targeting pathways important for these tumors in the hopes of further improving outcome.[1148] It should be noted that the sequence of treatment has been shown to be of major importance, with the best survival rates being achieved if radiation therapy is not delayed,[1149] although a recent study (Pediatric Oncology Group [POG] trial 9031) reported no difference in EFS in children who received radiation therapy first compared with those who received chemotherapy first in the presence of high-risk disease.[1150]

INFANT CHEMOTHERAPY. Patients younger than 3 years at diagnosis are considered to have higher risk disease at all stages and degrees of resection, related to the limitations of delivering craniospinal radiation therapy to this group. There is also an increased frequency of leptomeningeal dissemination at the time of diagnosis in young children (27% to 43%) versus older children (20% to 25%) with similar histologic diagnoses.[1151] After surgical resection, infants with medulloblastoma are often treated with chemotherapy alone or chemotherapy with involved field radiotherapy in an effort to reduce the high incidence of developmental and neuropsychological sequelae caused by craniospinal irradiation. It is clear that the risks of craniospinal radiation therapy in infants and young children are significantly greater than the benefits of therapeutic response in terms of neurocognitive development.[1152] Currently several chemotherapy regimens designed to delay or eliminate the need for whole-neuraxis radiation therapy are being investigated, including regimens using intraventricular chemotherapy.[1097] In addition high-dose regimens have been found to be feasible and effective for young children with disseminated medulloblastoma.[1153] The relative merits and risks of conventional multiagent chemotherapy compared with high-dose submyeloablative or myeloablative chemotherapy with stem cell support is under investigation.[348,728] An important finding in a recent study for infants with medulloblastoma is the particularly good outcome in infants with the desmoplastic variant, even without radiation therapy,[1097] suggesting that nodular desmoplastic medulloblastoma may represent a low-risk group that does well with less intensive therapy. These tumors are also commonly of the SHH subtype, and it is possible that integration of novel agents targeting this pathway may have a potential therapeutic role. Ongoing studies to confirm this finding are under way but raise the possibility that desmoplastic medulloblastoma may form a new low-risk group.

Prognosis

Patients with standard-risk medulloblastoma have a 5-year survival of approximately 75% to 90%, whereas 5-year survival in patients with high-risk medulloblastoma remains at between 40% and 60%.[1035,1129,1154] Infants with metastatic disease or bulky unresectable disease continue to do poorly, with a 3-year EFS of less than 40%, except in those with the desmoplastic variant. Patients with other rarer subtypes of medulloblastoma, including the large-cell, anaplastic, large-cell/anaplastic, and melanotic variants, continue to do poorly, even with maximal upfront therapy.[1092] Various histologic features associated with improved prognosis have been evaluated, of which nodular appearance appears to be most important.[1088] The presence of dissemination is the single most important factor that correlates with poor outcome.[1155] Lifelong repeated surveillance imaging is required in anticipation of radiation-induced secondary malignancies, such as a meningioma or HGG.[1156] Radiotherapy, particularly in young children, can also cause significant adverse late effects in neurocognitive development, growth, and endocrine function.[1146,1157,1158] Gene profiling of medulloblastoma was an accurate method of predicting outcome, even when evaluated in the context of clinical data. Variables such as age, M stage, and degree of resection did not significantly improve the predictive ability of this independent data set.[1159]

Relapsed Medulloblastoma

Relapses occur as failures at the primary site, at distant sites, or both. MRI is not always accurate when lesions are identified, and pathologic correlation is important in avoiding toxic therapy for patients whose disease has not actually progressed.[1160] Tumors occurring at the primary site within the posterior fossa may have a greater chance for salvage. Patients treated without upfront radiation therapy (infants, in particular) also have a good salvage rate.[1161] Retrieval therapy is rarely curative, but long-term disease control may occur with high-dose myeloablative chemotherapy in a small proportion of patients.[348,1162] Past experience has shown that patients entering high-dose chemotherapy without chemotherapy-responsive disease, or with residual disease at the time of transplantation, are unlikely to benefit from this approach. A large number of new intrathecal,[1163] biologic, and antiangiogenic agents are being evaluated for patients with relapsed medulloblastoma.[335,1164-1166] Although these agents are likely to be more effective when moved up early in the upfront setting, additional testing is still required. Most exciting are preliminary results with SHH inhibitors in this subgroup of patients.[1167] Given the distribution of mutations within the SHH pathway that differ between infants, children, and adults,[1050] as well as concerns for premature bone closure in infants and children taking these inhibitors, careful selection of patients and a balance of prognosis versus toxicity is required.

Future Directions

The recent discovery of genetic alterations defining different subtypes of medulloblastoma presents novel and exciting opportunities for the development of targeted therapies for children with medulloblastoma. Trials examining the efficacy of SHH inhibitors for those of the SHH subtype are currently under way, and novel agents that target the *MYC* transcription factor or activation pathways also are currently being investigated for MYC or MYCN amplified tumors. In addition studies that determine potential mechanisms by which medulloblastomas may acquire resistance to targeted agents are also important to provide insights into potential combination therapies.[1052,1168] Conversely treatment strategies that minimize long-term therapy-related morbidity in children with Wnt-positive medulloblastoma are also being investigated. The challenge in the coming era will be to develop strategies that incorporate risk stratification and biologically targeted agents in the upfront treatment strategy for children with medulloblastoma.

Pineocytomas and Pineoblastomas

Tumors of the pineal region are often grouped together based on their location rather than on their cellular origins and behavior. Embryonal tumors of the pineal region include pineocytoma, pineal parenchymal tumor of intermediate differentiation (PPTID), pineoblastoma, and papillary tumor of the pineal region (PTPR). Together they account for less than 5% of all pediatric CNS tumors. Other pineal-based lesions include GCTs and, less commonly, astrocytic tumors.[642] GCTs are discussed in a separate section. In a recent series of children diagnosed with pineal parenchymal tumors, the extent of surgical resection has been reported to be a significant prognosticator.[1169]

Pineocytomas

Pineocytomas arise from the pinocyte, the primary function of which appears related to photoreceptor activity and neuroendocrine function.[1170] They are classified as low-grade (grade I) neoplasms that are most common in adults and in late adolescence, although they can be observed in young children. They account for approximately 50% of the tumors of pineal origin, although pineal region neoplasms account for only 1% to 5% of all pediatric CNS tumors.[1171]

Clinical Presentation. Like other pineal region lesions, pineocytomas often present with a constellation of symptoms related to their location. This constellation includes obstructive hydrocephalus and Parinaud syndrome,[1172] a cluster of abnormalities of eye movements and papillary dysfunction characterized by paralyzed upgaze, pseudo–Argyll Robertson pupils, convergence-retraction nystagmus, eyelid retraction, and a conjugate downgaze “sunsetting” sign. Impairment of hypothalamic-pituitary, brainstem, and cerebellar function is also possible. Unlike malignant pineoblastomas, metastases are rare.

Imaging and Histology. On neuroimaging, pineocytomas are typically small focal lesions that can contain cysts and/or calcifications; they are best seen by CT. They are similar to other low-grade tumors on MRI, with strong contrast enhancement, hypointensity on T1-weighted sequences, and high signal intensity on T2-weighted sequences. Surgically these tumors tend to be well demarcated from surrounding tissue. Areas of hemorrhage are not uncommon. Microscopically pineocytomas are made up of small, round, mature-looking cells that have maintained features of pinocytes, including rosettes.[1173] These tumors demonstrate characteristic pineocytomatous rosettes that differentiate them from pineoblastomas. Mitoses are rare, as are other features of malignancy. Pineocytomas are usually strongly synaptophysin and neuron-specific enolase (NSE)–positive. If areas of pineoblastoma are identified with a pineocytoma, treatment is dictated by the most malignant element (i.e., pineoblastoma).

Management. Surgery remains the mainstay of the therapeutic approach for these lesions. Treatment directed at the hydrocephalus with third ventriculostomy may provide an opportunity to obtain a biopsy before aggressive and potentially morbid surgical resection is attempted.[1174,1175] Tumors with persistent growth can be irradiated, although the benefit of this treatment has not been clearly demonstrated. A role for chemotherapy has not been defined. Patients with incompletely resected tumors do not require therapy unless clear progression is demonstrated. Even patients with metastatic disease can remain untreated. The overall benign course observed with pineocytomas is in stark contrast to that of pineoblastomas.

Prognosis. The long-term prognosis remains excellent, even with incompletely resected disease. Conservative management should be followed with regard to attempted surgical resection and radiation therapy. Because almost all patients with pineocytomas will be long-term survivors, the need to avoid toxicity is paramount.

Pineal Parenchymal Tumor of Intermediate Differentiation

PPTIDs are tumors of the pineal region that occur at all ages, although they are frequent in middle age, and are classified as grade II or III, depending on pathologic features. They account for 20% of pineal region tumors and were formally identified in 1993. Although reports are limited, there appears to be a slight female preponderance. Genetic evaluation has demonstrated a large number of abnormalities.[1176]

Clinical Presentation. The presentation of patients with PPTID is similar to that of pineocytomas and includes obstructive hydrocephalus, as well as Parinaud syndrome,[1172] a cluster of abnormalities of eye movements and papillary dysfunction characterized by paralyzed upgaze, pseudo–Argyll Robertson pupils, convergence-retraction nystagmus, eyelid retraction, and conjugate downgaze. Impairment of hypothalamic-pituitary, brainstem, and cerebellar function is also possible. Unlike pineocytomas, metastatic disease appears to be slightly more frequent.

Imaging and Histology. Imaging characteristics are similar to those of other lesions of pineal origin. They are cellular lesions with moderate nuclear atypia and a low mitotic index.[1177] Because of sampling error, diagnosis can be difficult with limited tissue, especially tissue obtained via third ventriculostomy.

Management. Because of the increasing degree of malignant potential when compared with pineocytomas, attempts at surgical resection should be considered. Although formal pediatric studies are lacking, radiation therapy and chemotherapy should be considered. Intensity of treatment can be based on the localization of the tumor (focal, invasive, or disseminated), as well as the proportion of mitoses, necrosis, atypia, and possibly neurofilament protein expression.[1178]

Prognosis. A definite prognosis for PPTID has not been clearly established. Grade is likely to play an important part in the long-term outcome of patients, as is the size and metastatic stage of patients.[1179] Because these tumors span all age groups, large homogeneous studies are difficult to perform.

Pineoblastoma

Unlike pineocytomas, pineoblastomas are highly malignant embryonal tumors. Like other small round blue cell tumors, these lesions are considered WHO grade IV and have a high propensity to metastasize. Typically they are observed in children younger than those seen with pineocytomas, although considerable overlap exists. Pineoblastomas can be associated with the genetic form of retinoblastoma and in such cases are often referred to as trilateral retinoblastomas.[1180] In a recent study of 408 patients with retinoblastoma, pineoblastoma was detected in 1% of all patients.[1181] An association with familial adenomatous polyposis has also been reported.[1182] Little is known about the molecular classification of these tumors with respect to their genesis or their association with other neural tumors of the CNS (PNET or medulloblastoma).[1183] Defects in *TP53* have not been reported.

Clinical Presentation. Presenting symptoms of pineoblastoma are virtually identical to those for pineocytomas, although the duration of symptoms may be shorter than that seen for other tumors in this location. Pineoblastomas often present with a constellation of symptoms related to their location, including obstructive hydrocephalus in most patients,[1184] as well as Parinaud syndrome,[1172] a cluster of abnormalities of eye movements and papillary dysfunction, as previously described. Impairment of hypothalamic-pituitary, brainstem, and cerebellar function is also possible. Pineoblastomas have a much greater propensity to metastasize and thus may demonstrate symptoms beyond the pineal region.

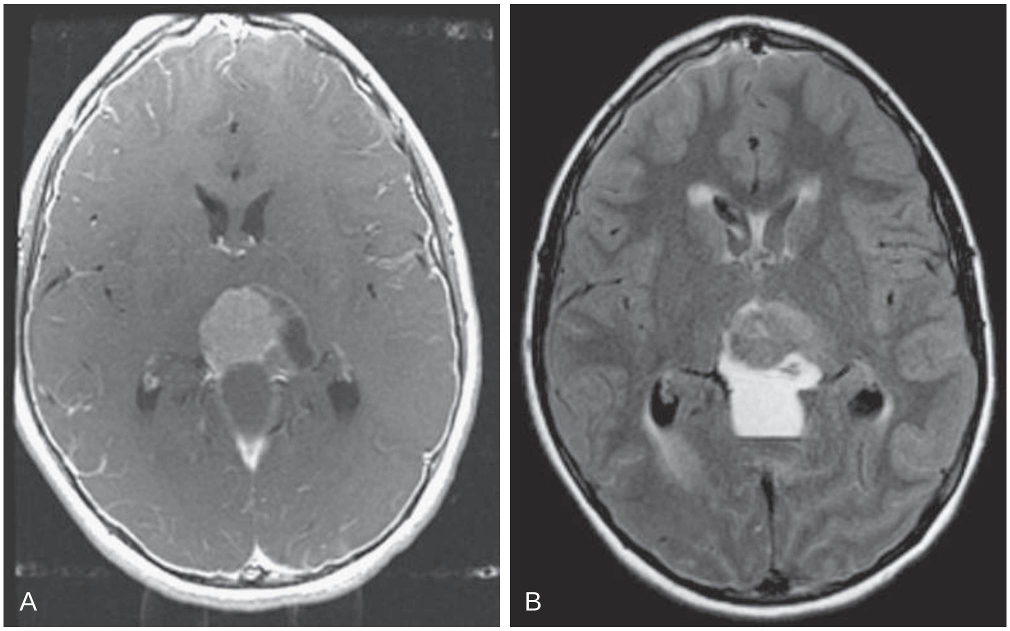

Figure 57-40 A large contrast-enhancing pineoblastoma. **A,** An axial T1-weighted image with use of contrast material. **B,** An axial fluid-attenuated inversion recovery image demonstrating a bright T2-weighted signal.

Imaging and Histology. The neuroimaging characteristics of pineoblastomas are not pathognomonic for these tumors, but they are differentiated from pineocytomas by a significant increase in the volume of the tumor and the presence of much less distinct boundaries. MRI characteristics include low signal on T1-weighted sequences and heterogeneous areas of contrast enhancement (Fig. 57-40).[1185] T2-weighted signals may be lower than in pineocytomas because of the higher nuclear-to-cytoplasmic ratio evident in these more malignant tumors.[1186] On histologic analysis these tumors are similar to other small round blue cell tumors, composed of sheets of cells but lacking the characteristic pineocytomatous rosettes of pineocytomas.[1187] Pineoblastomas are typically synaptophysin- and NSE-positive and other markers, including those for photoreceptor pathways, can be present, consistent with the developmental role of the pineal gland.[1178,1188] Homer-Wright rosettes (i.e., cells with a central zone of cytoplasm; see Fig. 57-39) and Flexner-Wintersteiner rosettes (i.e., cells with a central zone of cytoplasm and a central space; Fig. 57-41) are common, but these rosettes can be seen in a large number of other embryonal tumors. These tumors often have significant atypia, and mitotic activity can be high. When additional pathways of differentiation are present (e.g., melanin, cartilage, and muscle), the tumors are called pineal anlage tumors. Regions of pineoblastoma can also be identified as part of a pineocytoma and are treated as a pineoblastoma. Although sporadic pineoblastoma has no clear genetic association, patients with hereditary (bilateral) retinoblastoma have a significant incidence of pineoblastoma (trilateral retinoblastoma). The clinical course of retinoblastoma-associated pineoblastoma can differ from that of sporadic pineoblastoma.[1189]

Recent profiling of genomic alterations have reported copy number alterations observed in pineoblastoma. These alterations include loss of chromosome 16q and amplification of PCDHGA3, and FAM129A.[1169] In addition DNA copy number profiles have reported more similarities between sPNETs and pineoblastoma than between these tumors and the lower grade tumors of the pineal region.[1190] The development of pineoblastoma has also been reported in a young patient with a germline mutation of *DICER1*, which is also associated with the development of pleuropulmonary blastoma.[1191]

Management. The therapeutic approaches for pineoblastoma have followed those of other embryonal seeding

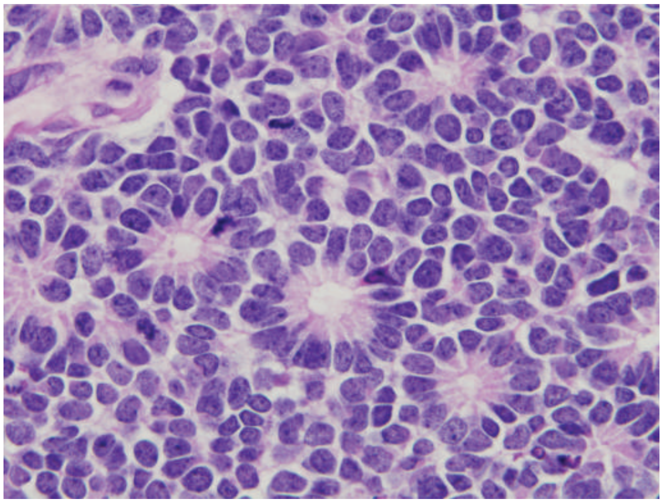

Figure 57-41 Flexner-Wintersteiner rosette in a patient with pineoblastoma (hematoxylin and eosin; ×600).

tumors of the CNS. The workup of patients with pineoblastoma includes immediate intervention for obstructive hydrocephalus and assessment of risk for herniation. A rapid CT or MRI scan, in conjunction with the examination and presenting history, will permit the neurosurgeon to assess these risks. If urgent CSF shunting is not required, then completion of the imaging baseline workup, including MRI of the brain and spine, can be performed and surgical resection can be planned. Unlike medulloblastoma, the location of pineoblastomas with adjacent vascular structures makes exploratory surgery much more risky, and referral to a highly specialized center should be considered. A third ventriculostomy or VP shunt should be deferred prior to initial surgery but may be necessary if sufficient resection with reestablishment of CSF flow is not achieved. In many patients an endoscopic biopsy of the tumor to confirm the diagnosis and concurrent third ventriculostomy can be performed with a planned open craniotomy and resection once the patient is clinically stable, the disease has been defined, and possible presurgical chemotherapy has been provided.[1174] Patients with metastatic disease at diagnosis should not undergo upfront aggressive surgery because adjuvant therapy will be required. For patients with focal disease at diagnosis based on initial MRI and documentation of negative results of a lumbar puncture, complete removal of the tumor ultimately will be an important component of long-term prognosis[1192] but should not be undertaken at any costs. Consideration for staged surgeries (second- and even third-look approaches) may be equally effective without causing permanent neurologic damage.

As with other embryonal seeding tumors of the CNS, craniospinal radiotherapy is an important modality in treating microscopic metastatic disease at presentation. Unlike medulloblastoma, pineoblastomas do not have a standard-risk category. All patients require aggressive therapy, including a craniospinal dose of 3600 cGy and a focal boost to the primary site of 5400 to 5940 cGy. Sites of metastatic disease require radiation boosts as well. Even with focal resectable disease, the prognosis for pineoblastoma falls significantly below that of medulloblastoma.[1184] In persons with disseminated disease, especially diffuse leptomeningeal spread, and infants, for whom craniospinal radiotherapy is contraindicated, the prognosis remains especially poor. The use of SRS or other similar modalities to deliver single-fraction ablative radiation therapy may provide added disease control of unresectable tumor, although these approaches are limited to small areas of disease.

Chemotherapy is an important modality for patients with pineoblastoma, and significant responses to chemotherapy have been observed, including in patients with trilateral retinoblastoma.[1193] Results from infant studies, which deferred radiotherapy, demonstrated that although chemotherapy can be effective at reducing bulk disease, few patients are long-term survivors with this modality alone.[1194] Because of the rarity of this entity most protocols have combined these patients with patients who have other embryonal tumors, including CNS PNETs and, occasionally, medulloblastoma. Specific estimates of survival from different therapies have therefore been difficult to determine. Current approaches continue to include initial craniospinal radiotherapy in combination with chemotherapy, followed by postradiation chemotherapy. Most regimens have used combinations of vincristine, cyclophosphamide, cisplatin, and etoposide.[1192] Because of the chemoresponsiveness of these tumors, pilot clinical trials with high-dose chemotherapy with stem cell transplantation have also been undertaken. The results of the German HIT2000 clinical trial, which included children with CNS PNET and pineoblastoma, recently reported 5-year EFS and OS of 24% ± 10% and 40% ± 12%, respectively, with multiagent chemotherapy and radiation therapy.[1195] Children with high-risk disease received intensified therapy.

The concurrent use of craniospinal radiation therapy and multiagent chemotherapy for pineoblastoma has resulted in a significant impairment of nutrition during therapy for these patients.[1142] A large number of patients will require nutritional support through a nasogastric tube or, more commonly, a gastric tube. Constant surveillance of nutrition is important because these issues are often dismissed early and are only recognized when severe weight loss has occurred. Patients with persistent vomiting usually initiate therapy in a negative nutritional state.

Prognosis. The outcome of patients with pineoblastoma remains poor. Patients with focal disease that can be completely resected have 3- and 5-year EFS of approximately 50%.[1184,1192] Infants, patients with incompletely resected disease by the end of therapy, or patients with metastatic disease continue to do poorly, with 3- and 5-year EFS estimates of 20% or lower. Progression tends to occur early and can occur at the primary site, throughout the CNS, or both. A recent study of recurrence patterns in children with embryonal intracranial tumors noted a high rate of relapses that involved the spine in children with pineoblastoma.[1196] Extracranial metastases are uncommon. Some patients with metastatic disease, however, are long-term survivors.[1192] After recurrence, no standard therapy has been documented to be effective, and most patients will succumb to their disease, usually within months.

Papillary Tumors of the Pineal Region

PTPRs are rare tumors of children and adults that were separated from other pineal tumors in 2003.[207,1197] As the name implies these neuroepithelial lesions possess papillary structures and are thought to be derived from specialized ependymal cells. Because of their varied appearance, they can be confused with ependymomas, choroid plexus tumors, and pineocytomas.[1198] PTPRs appear to fall into the WHO grade II or III category.

Clinical Presentation. The clinical presentation of PTPRs is similar to that of other lesions of the pineal area. Hydrocephalus is present in almost all patients, and Parinaud syndrome[1172] is common. Impairment of hypothalamic-pituitary, brainstem, and cerebellar function is also possible. Metastatic disease does not appear to be as prevalent as in pineoblastomas.

Imaging and Histology. PTPRs are well-circumscribed, often cystic lesions. They are hyperintense on T1- and T2-weighted sequences and enhance with administration of contrast material.[1199,1200] Histologically these tumors stain strongly for keratins and are usually negative or weakly positive for GFAP (in contrast to ependymomas) and synaptophysin.[1201] Most of the tumor cells show strong expression of NSE, cytokeratins (particularly CK18), S-100 protein, and vimentin. The mitotic index and MIB1 labeling index are intermediate but of unclear prognostic significance.[1202]

Management. In spite of their differentiated appearance, PTPRs are aggressive tumors that are not highly responsive to therapy.[1203] In a recent report of 31 patients, 21 of whom achieved a gross total resection, adjuvant radiation therapy alone resulted in a PFS rate of only 27%.[1204] The ability of achieve a gross total resection has been reported in some studies to be associated with improved PFS.[590,1203]

Prognosis. In spite of complete resection and focal radiation therapy, local recurrences are common,[1205] although patients with complete removal of these tumors may do better.[1206] Dissemination appears rare, and craniospinal radiation therapy therefore does not appear to be required. Patients with an elevated MIB1 labeling index or mitotic rate may tend to do worse.[1207]

Supratentorial or Central Nervous System Primitive Neuroectodermal Tumors

Supratentorial or CNS PNETs are tumors of neuroepithelial origin.[1208] The classification of CNS PNET (previously called sPNET) as separate from medulloblastoma and other embryonal tumors, which was initially proposed in 1973,[1031] has not been without controversy. Historically these tumors have been called by various names, including cerebral medulloblastoma, cerebral neuroblastoma, and cerebral ganglioneuroblastoma. Rorke[1209] (1983) proposed that these tumors are the supratentorial equivalent of medulloblastoma, another common embryonal neoplasm. Although these tumors are histologically similar to medulloblastoma, they respond poorly to medulloblastoma-specific therapy. Part of the confusion in the approach to CNS PNETs has been in the nomenclature—the overlap in the term "PNET" for tumors of the body as well. These tumors do not share the molecular pathways,[1183] metastatic sites, or treatment responses of the extracranial PNET tumors. Even within the CNS, PNETs likely represent a heterogeneous group of tumors.[1029] According to the WHO classification schema,[1210] a number of subtypes of PNET are recognized: classic PNET, PNET with neuronal differentiation (called cerebral neuroblastoma), and, if ganglion cells are present as part of the tumor, cerebral ganglioneuroblastoma. Neither of the latter two entities is related to classic neuroblastoma, which is typically identified around the adrenal gland and shares a common name as a result of historical nomenclature only. New molecular determinants associated with PNETs of the brain have been identified using molecular and proteomic analysis and will, it is hoped, be useful for better subclassification of the diseases that fall into this broad category of tumors.[306,1211-1213] Recently gene expression and genomic profiling efforts of CNS PNETs have confirmed that this disease entity is heterogenous and consists of multiple different tumor types. Copy number analyses of PNETs have in general revealed a complex karyotype with frequent copy number alterations.[1190] In addition these efforts have highlighted the inherent difficulty in classifying tumors based on histology. Molecular profiles have been found to match those of other tumor types, including ATRT (characterized by loss of INI1) and HGGs (characterized by the presence of mutations in the histone genes). Importantly, clustering of profiles have revealed that tumors have distinct profiles based on the underlying lineage of the tumor, including primitive neural, oligoneural, and mesenchymal lineages.[1214] These groups are associated with differences in clinical courses and prognosis, with tumors with an underlying primitive neural profile exhibiting the worse prognosis. Further, these profiling studies have shed light on other genes that may be involved in the pathogenesis of these brain tumors and thus may represent candidates for targeted therapies. These therapies include amplification of genes involved in cell cycle regulation.[1063]

CNS PNETs are relatively rare, occurring at a rate that is approximately 10% to 20% that of medulloblastoma.[1215] Precise statistics regarding incidence are difficult to ascertain because of historically different views regarding classification and nosology. These tumors are more common in early childhood, with most patients diagnosed before the age of 10 years,[1216] and white persons make up most of the reported cases. Most cases are identified in early childhood, but they span all ages. Although they are classified as supratentorial in nature, these tumors have been identified in the infratentorial and spinal compartments. A better term has recently been adopted by WHO[207]—*CNS PNET*.

Clinical Presentation

Presenting features of CNS PNETs depend on the location of the lesion. Those adjacent to the ventricular flow path will usually include signs and symptoms of raised ICP as a result of obstructive hydrocephalus. Specific neurologic signs are dependent on the anatomic structures adjacent to the tumor and can include seizures, mood changes, or hemiparesis. Metastases are frequent in CNS PNETs, and clinical symptoms unrelated to the primary site of disease require investigation.

Imaging and Histology

CNS PNETs appear similar, independent of location within the CNS. As in medulloblastoma and pineoblastoma, these tumors can have areas of cyst or necrosis evident on CT or MRI. Lesions are dark on T1-weighted sequences unless hemorrhage is present and dark on T2-weighted sequences, reflecting their high nuclear-to-cytoplasmic ratio.[1217] CNS PNETs are usually contrast-enhancing after administration of gadolinium (Fig. 57-42). Edema, as evident on T2-weighted or FLAIR sequences, is often prominent. All CNS PNETs are

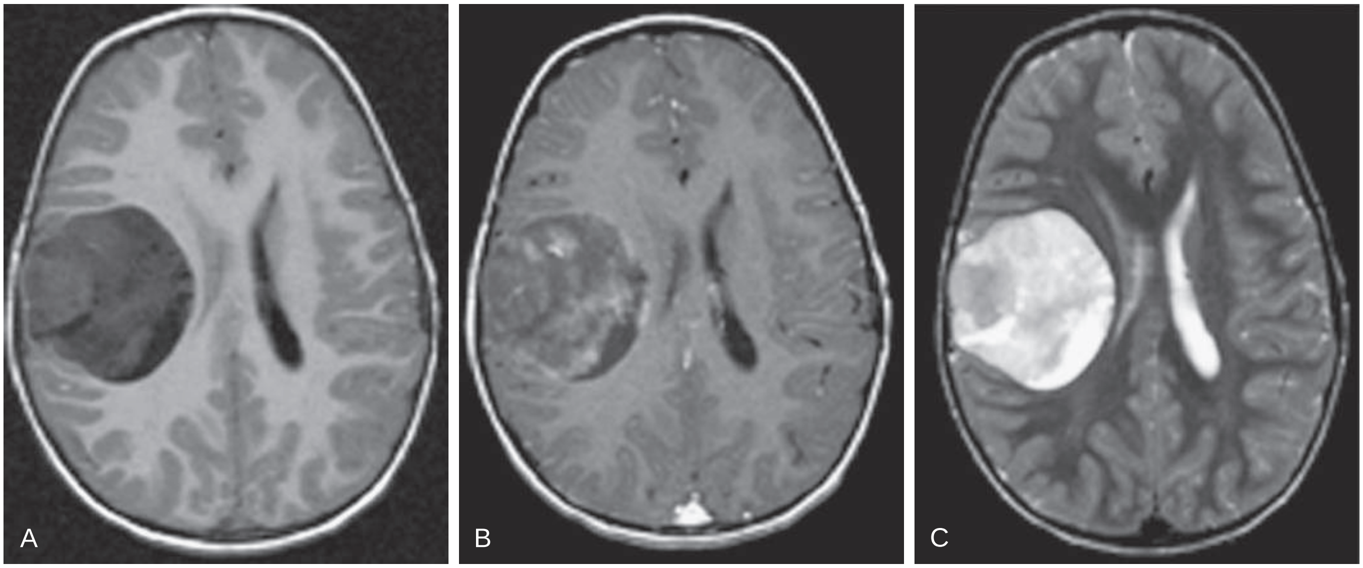

Figure 57-42 Primitive neuroectodermal tumor. **A,** An axial T1-weighted image without use of contrast material. **B,** An axial T1-weighted image with use of contrast material. **C,** An axial T2-weighted image.

considered WHO grade IV. The light microscopic features of CNS PNETs can be similar to those of medulloblastoma or pineoblastoma. Tumors are characterized by the presence of neuroepithelial cells. Many CNS PNETs have evidence of differentiation along glial, neuronal, ependymal, or oligodendroglial lines, although most (approximately 60%) appear undifferentiated.[1218]

Immunohistochemical markers of CNS PNETs include synaptophysin, B-tubulin, and S-100. Occasionally GFAP can be identified in these tumors and indicates their ability to undergo divergent differentiation. Mitotic rates are often high and, although variable, the MIB1 labeling index is usually abundant. Mutations of p53 are rare[1219] and were identified in only 3 of 28 cases of CNS PNET in one study, although many tumors had overexpression of wild-type p53, which correlated with a poor prognosis.[1220] Specific markers for CNS PNETs that distinguish them from medulloblastoma do not exist. Other features, such as Homer-Wright rosettes and perivascular pseudorosettes (i.e., cells around a central blood vessel) are observed in many different tumors (see Figs. 57-35 and 57-39). ATRTs may resemble PNETs, but the presence of cells that stain positively for myosin but lack the protein produced by the *SMARCB1* (*hSNF5/INI1)* gene are diagnostic features for ATRT.[1221,1222]

Medulloepitheliomas, Ependymoblastomas, and Embryonal Tumors with Abundant Neuropile and True Rosettes

Historically medulloepitheliomas, ependymoblastomas, and embryonal tumors with abundant neuropile and true rosettes (ETANTRs) have been considered distinct subtypes of CNS PNETs. However recent genomic and gene expression profiling efforts, including genome-wide DNA methylation and copy number profiling, have revealed similarities in genomic profiles, suggesting that they may represent spectrums of the same biologic entity.[1223] In this study, which included 97 tumor samples, all tumors were found to strongly express LIN28A, which had previously been described in ETANTRs.[1224,1225] No difference in clinical features was observed, and unsupervised hierarchical clustering did not reveal subgroups for 41 tumors with sufficient material to perform the analysis, while as a group the tumors clearly separated from other pediatric brain tumors. Finally 95% of tumors were found to harbor amplification of chromosome 19q13.42, previously associated with embryonal tumors with multilayered rosettes.[1226-1228] This study suggests that these entities share the same biology and can be considered spectrums of the same disease. However we will describe the traditional classification and clinical features of these tumors, in keeping with the current WHO classification.

CNS PNET tumors that have re-created features of the neural tube, called medulloepitheliomas, are typically found in very young children[1229] and have even been reported in newborns. They can occur throughout the brain, spine, and optic tract[1230] and can also occur outside the CNS. Their imaging characteristics differ somewhat from other CNS PNETs, with bright appearance on T2-weighted imaging.[1231] They tend to be large on macroscopic imaging. Additional immunohistochemical markers include nestin and vimentin staining.[1210] As with other CNS PNETs, maximal surgical resection, chemotherapy, and radiation therapy are the cornerstone of therapy.[1232] The predilection for young age in this subset of PNETs limits the use of craniospinal radiation.

PNET tumors with ependymoblastic rosettes are called ependymoblastomas and have features that overlap other CNS PNETs.[1223] These tumors predominate in infants and young children[1233] and can be found throughout the CNS, although most are associated with the ventricular system.[1210] Dissemination throughout the CNS is common,[1234] and symptoms include obstructive hydrocephalus, enlarging head circumference in infants, and focal neurologic deficits. The MRI appearance is similar to that of other PNETs, and edema is commonly observed.[1235] Treatment mirrors that of other CNS PNETs. Maximal resection is paramount, followed by multiagent chemotherapy. Although craniospinal radiation therapy is likely important for outcome, the prevalence of ependymoblastoma in infants precludes its use. Prognosis is poor, with rapid disease progression in most patients.

ETANTR is another rare CNS PNET tumor with a spectrum of histologic features and chromosomal abnormalities.[1210] These lesions can be large, cystic, and calcified and come to clinical presentation as a result of mass effect.[1236] Their rarity makes treatment recommendations difficult, although most are approached in a manner similar to that of other PNETs of the brain. The presence of isochrome 17[1237] in only a few cases suggests that they are biologically distinct from medulloblastoma.[1238] Various cytogenetic abnormalities have been defined.[1239]

Cerebral Neuroblastomas

PNETs with neuronal differentiation are called cerebral neuroblastomas and are rare tumors of infancy and childhood. They are unrelated to the more prevalent peripheral sympathetic nervous system form of neuroblastoma and predominate in young infants,[1240] occurring in both the cerebrum[1241] and posterior fossa.[1242] Lack of immunohistochemical staining with IGF2 and IGF type 1 receptor, which is positive in many other infant CNS tumors, can help with the diagnosis.[1210,1243]

A related entity of cerebral neuroblastoma is termed *ganglioneuroblastoma*, which has the presence of ganglion cells in addition to the neuronal component.[1210] These tumors cannot be differentiated from other malignant seeding tumors of infancy by MRI characteristics.[1244] Unlike most other CNS PNETs, cerebral neuroblastoma and CNS ganglioneuroblastoma may have a better prognosis[1245] with surgery and chemotherapy.

Treatment Strategies

A number of treatment protocols based on the successful therapeutic approaches of medulloblastoma have been applied to CNS PNETs.[1148] Repeated studies using maximal surgery, high-dose craniospinal radiotherapy to 3600 cGy with a boost to the primary site of at least 5400 cGy, and multiagent chemotherapy have not fared as well for CNS PNETs[1246,1247] as for high-risk medulloblastoma, with 4-year survival of approximately 40% in one retrospective series.[1216] In one study of 55 patients treated with maximal surgery, craniospinal radiation therapy, and CCNU, vincristine, and prednisone versus 8-in-1 chemotherapy sandwiched in the middle, OS and EFS were comparable. The 3-year EFS was approximately 50% in the two groups and thus appeared similar to that reported in other studies. Poor prognostic variables included the presence of metastases and age younger than 2 years. Patients with pineoblastoma did better, with an estimated 3-year PFS of 65%.[1247] Compared with medulloblastoma, CNS PNETs often respond poorly to medulloblastoma-specific therapy, despite the fact that they are histologically similar.[1248] The use of high-dose chemotherapy with stem cell rescue has been successful for some young children in eliminating the need for radiation therapy, with 5-year EFS of 39%.[1249] The exact conditioning regimen and number of cycles of intensive chemotherapy remain under investigation.[1250] Recurrences are often disseminated,[1248,1251] even when craniospinal radiation therapy is delivered upfront, and the salvage rate for these patients is exceedingly poor. In spite of these overall poor results, there have been reports of survivors after surgery, especially GTR, and radiation therapy.[1252] In one study patients treated with surgery, radiation therapy, and high dose stem cell–supported chemotherapy were reported to have a 5-year EFS of 75% ± 17% and an OS of 88% ± 13%.[1253] For patients with high-risk metastatic disease, the use of adjuvant carboplatin with radiation therapy as a radiosensitizer has been pilot tested in a phase I/II trial with promising results[1254] and is currently undergoing further investigation by the COG.

The concurrent use of craniospinal radiation therapy and multiagent chemotherapy for CNS PNETs has resulted in a significant impairment of nutrition during therapy for these patients.[1142] Therapy is intensive, and supportive care is important. A large number of children will require nutritional support through a nasogastric tube or, more commonly, a gastric tube. Constant surveillance of nutrition is important because these issues are often dismissed early and are only recognized when severe weight loss has occurred. Patients with persistent vomiting may initiate therapy in a negative nutritional state.

Prognosis

Although the prognosis of CNS PNET is well below that of medulloblastoma, 40% of patients will be long-term survivors. The most important variable for prolonged survival is the ability to achieve a complete resection in patients with nonmetastatic disease, followed by CSI and multiagent chemotherapy. The success of salvage therapy in patients who have had a relapse is exceedingly poor, even with high-dose chemotherapy and stem cell rescue.[1255,1256]

Atypical Teratoid Rhabdoid Tumors

ATRTs are uncommon, highly malignant tumors seen primarily in infants and in young children,[1257-1259] with a peak incidence between birth and 3 years. Cases throughout childhood[1260] and in adults have been reported,[1261] however, as has hereditary transmission of the susceptibility gene, resulting in congenital disease.[1262] Although CNS ATRTs account for approximately 1% to 2% of childhood brain tumors, they represent almost 10% of CNS tumors in infants.[1263,1264] Rhabdoid tumors may arise anywhere in the body but are most common in the kidney, CNS, and soft tissues. CNS ATRTs are most commonly identified in the posterior fossa (60%) at the cerebellopontine angle, although supratentorial ATRTs are also frequently seen.[1265] Pineal, spine, and suprasellar area ATRTs have also been reported. This tumor has a strong male preponderance, and metastases at diagnosis are common.[1265]

ATRTs have a spectrum of morphologic and molecular variants,[1266] but the hallmark of this disease is the loss of the *SMARCB1* (also known as *INI1*, *SNF5*, and *BAF47*) gene product on chromosome 22 as a result of biallelic inactivating mutations.[1267] Since the original description of monosomy 22 in ATRTs, this tumor suppressor gene has been cloned from this region[1268] and encodes a core subunit of the SWI/SNF chromatin remodeling complex.[1267] Recent publications have reported on the absence of other canonical pathway mutations and the extremely low mutation rates found in these tumors, thus demonstrating the remarkably simple genome of malignant rhabdoid tumors.[1269,1270]

Mutations and loss of the *SMARCB1* gene and protein expression may not be confined to ATRTs alone because reports on choroid plexus carcinoma, CNS PNET, and medulloblastoma have been reported,[1257] along with a recently identified entity, cribriform neuroepithelial tumor.[1271] Whether these later reports represent other diseases with *SMARCB1* mutations or atypical cases of rhabdoid tumors is controversial. Other diseases such as familial schwannomatosis, multiple meningiomas, epithelioid sarcomas, and extraskeletal myxoid chondrosarcomas are known to have loss of SMARCB1.[1272-1275] In addition, mutations in other subunits of the SWI/SNF chromatin remodeling complex (AT rich interactive domain 1A [ARID1A], polybromo 1 [PBRM1], and BRG1) have also recently been identified in neuroblastoma and ovarian, kidney, and lung cancers.[1276-1280]

Clinical Presentation

Presenting symptoms are dependent on the age and location of the tumor. In persons with posterior fossa tumors, obstructive hydrocephalus with headaches, morning vomiting, and long tract signs is common. Because most patients are young, irritability, lethargy, or failure to thrive may be evident. In patients without closed fontanelles, rapidly enlarging head circumference is observed. Cranial nerve dysfunction is common, resulting in head tilt and diplopia. Patients with supratentorial tumors will often have obstructive hydrocephalus because of the rapid growth and concurrent cysts that obstruct CSF flow. Additional symptoms can be referred to direct compression of neural structures adjacent to the tumor and thus are dependent on location.[1265,1281] Although uncommon spinal ATRT can occur and present with focal motor deficits. Because of the high incidence of metastatic disease, patients with symptoms related to a specific area away from the primary tumor site require thorough investigation. Although rare constitutional loss of the *SMARCB1* gene (or the *INI1* gene; the nomenclature is interchangeable) can occur,[1263] resulting in intracranial and metachronous extraneural disease. Patients should therefore undergo CT evaluation of the chest, abdomen, and pelvis.

Imaging and Histology

Imaging characteristics are similar to those of other neuroectodermal tumors (medulloblastoma and PNET) of the CNS,[1282] including isointense appearance on T1-weighted MRI and heterogeneity on FLAIR and T2-weighted sequences.[1283,1284] Cystic areas are common. Tumors are usually heterogeneously enhancing with contrast administration. Because of their high cellular composition, restricted diffusion is often observed. The presence of hemorrhage and calcifications is not uncommon.[1285]

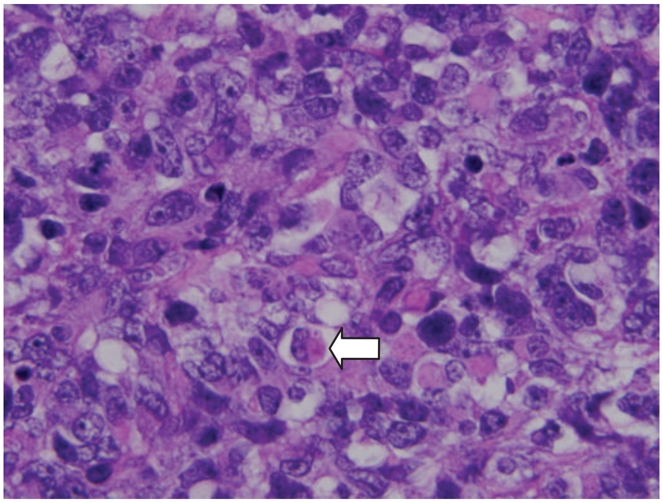

Figure 57-43 An atypical teratoid rhabdoid tumor *(arrow)* demonstrating prominent nucleoli and eosinophilic globular cytoplasmic inclusions (hematoxylin and eosin; ×600).

ATRT has been recognized as a distinct pathologic entity, and it is differentiated from medulloblastoma and other CNS PNETs.[1286] This distinction has been supported by findings of deletions or loss at chromosome 22q11.2, the identification of the tumor suppressor gene *SMARCB1*, and the finding of germline and somatic mutations of *SMARCB1* in approximately 75% of cases of CNS ATRTs,[1287] although ATRTs based on morphologic criteria with normal expression of *SMARCB1* have been identified.[1288] Rhabdoid cells have the characteristic appearance of an eccentric nucleus, prominent eosinophilic nucleoli, and abundant cytoplasm, with an eosinophilic globular cytoplasmic inclusion (Fig. 57-43).[1289] These cells stain with EMA and vimentin. GFAP and synaptophysin can also be positive.

SMARCB1 (also known as *INI1* or *BAF47*) staining is routinely used to confirm the diagnosis and has become a standard assessment tool for making the diagnosis of ATRT in atypical cases.[1222] The expression of this nuclear protein, which remains expressed in endothelial cells, is characteristically lost in tumor cells (Fig. 57-44). Tumors without the presence of rhabdoid cells but with loss of *SMARCB1* staining are still considered ATRTs.[1288] Whether choroid plexus tumors can have loss of *SMARCB1* expression or whether these tumors represent actual ATRTs is controversial.[1221,1290] ATRTs are classified as WHO grade IV[1289] lesions with an elevated MIB1 labeling index and are composed of primitive neuroepithelial, epithelial, and mesenchymal components. Large areas of small round blue cells can predominate, resulting in the misdiagnosis of medulloblastoma or CNS PNET. In a review of 55 cases from a POG study, the small round blue cell component resembled medulloblastoma,[1291] and ATRT was misclassified as medulloblastoma in more than 50% of cases.[1257] These findings emphasize the need for confirmatory testing with *SMARCB1* immunohistochemical staining or fluorescence in situ hybridization to look

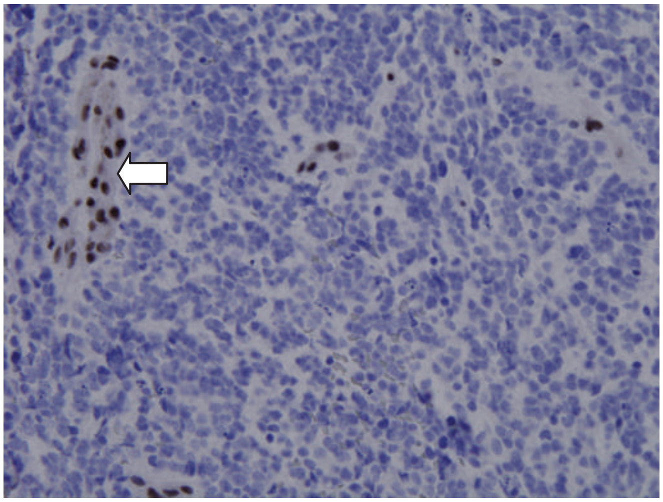

Figure 57-44 An atypical teratoid rhabdoid tumor with absence of switch/sucrose nonfermentable–related, matrix-associated, actin-dependent regulator of chromatin, subfamily b, member 1 (SMARCB1; INI1) immunoreactivity in the tumor cells. Normal endothelial cells within the blood vessels have normal SMARCB1 expression *(arrow;* SMARCB1 immunostaining; ×400).

for monosomy chromosome 22 to help confirm or exclude the diagnosis of ATRT.[1291] Similarly a central pathology review of 227 of 284 eligible infants with brain tumors from a CCG clinical trial for infant patients (trial 9921) showed that ATRT is a significant component of the tumors in this population and that frequent misdiagnoses occur.[962] Given the predominance of *SMARCB1* loss of expression in ATRT, it is now standard practice to evaluate *SMARCB1* expression for treatment stratification onto the appropriate disease-specific protocols.

Management

Multimodality protocols developed for the treatment of medulloblastoma have not been effective for ATRTs. Some success has been achieved by using treatment protocols based on therapy for children with rhabdomyosarcoma[1281,1292] and high-dose myeloablative chemotherapy.[1265,1293,1294] Currently the optimal therapy for pediatric ATRT remains maximal surgical resection, multiagent chemotherapy, and radiation therapy.[1260,1295] Older patients appear to have a better prognosis and, with complete surgical resection, multiagent chemotherapy, and craniospinal radiotherapy, they have 2-year EFS and OS of 78% and 89%, respectively. In contrast children younger than 3 years have a dismal outcome with EFS and OS of 11% and 17%, respectively.[1260] A recent risk-adapted treatment protocol in which patients received maximal surgery, multiagent chemotherapy, both systemic and intrathecal, and focal radiation therapy in children younger than 3 years and CSI in older patients has demonstrated encouraging results. The 2-year EFS and OS in this group of patients, most of whom were younger than 3 years, was 53% and 70%, respectively.[1295] These results indicate that ATRT can be effectively treated and that even patients with metastatic disease can be long-term survivors. The need for radiation therapy in the treatment of ATRT remains controversial, especially for the youngest patients, although some centers have encouraged its use.[1296] The overall positive outcomes seen in infants treated with 3D-conformal therapy, as well as those treated with high-dose chemotherapy and a stem cell transplantation approach without radiation therapy, suggest that craniospinal radiotherapy is not needed in all patients. The identification of a radiation-resistant CD31-positive stem cell may explain some of the innate resistance of this tumor to current therapies.[1297] It is hoped that the continued discovery of the function of the *SMARCB1* tumor suppressor gene, coupled with an improved understanding of the pathways aberrant in these tumors, will lead to more specific targeted therapies.[1298]

Prognosis

Until recently estimates of survival rates for ATRT ranged from 6 to 11 months.[962,1291,1299,1300] CNS ATRT tumors tend to have specific mutational hotspots in the *SMARCB1 (INI1)* gene,[1301] although treatment response and outcome are not known to be influenced by specific mutations. Although tumors tend to be initially responsive to chemotherapy, recurrence rapidly occurs, both locally and with metastatic disease.[1287] However the prognosis for patients with ATRT may be improved dramatically with intensive multimodality treatment.[1260,1295] Although survival is extremely uncommon, some survivors of relapsed disease have been reported.[1281]

Neurocytomas

Central neurocytomas are rare tumors, comprising between 0.25% and 0.5% of all brain tumors.[1302,1303] First described in 1982 by Hassoun and colleagues, neurocytomas typically occur in adolescents and young adults. These tumors are of neural lineage based on the expression of neuronal markers such as βIII-tubulin, neural cell adhesion molecule, NSE, and synaptophysin.[1304,1305] A gene expression profile comparison of central neurocytoma cells with normal adult VZ progenitors has demonstrated significant overlap, indicating that central neurocytoma is most consistent with proneural cells and that these neurocytoma cells differ from progenitor cells by the increased expression of IGF2 and receptors and effectors of the canonical Wnt signaling pathway and *PDGFR*.[1306] Neurocytomas usually arise in the lateral ventricles, especially in proximity to the third ventricle and foramen of Monro, and are called central neurocytomas. Those localized to the brain parenchyma are called extraventricular neurocytomas. Historically neurocytomas have been frequently described as benign lesions because of the positive outcome of patients with complete surgical resections, although aggressive behavior and poor outcome are not uncommon.[1307,1308] Furthermore numerous reports have been made of tumors with MIB1 labeling indices greater than 3%[1309] and/or atypical histologic features such as increased mitotic activity, vascular proliferation, and/or focal necrosis.[1310] The mean age at presentation in adults is 28 to 29 years, with most patients between the ages of 20 and 40 years,[1302] and a male-to-female ratio of 3:2.[1311] A review of neurocytoma in 60 children younger than 18 years, compiled primarily from reports in the medical literature, has demonstrated a median age of 16 years, with a similar male predominance (61%).[1312]

Clinical Presentation

Most neurocytomas are located in the ventricular system,[1313,1314] specifically the anterior portion of the lateral ventricles near the foramen of Monro, although extraventricular tumors have been described.[1308,1315] Symptoms of raised ICP are common as a result of tumor obstruction of CSF flow at the level of the foramen of Monro or cerebral aqueduct.[1307,1314] Patients with neurocytoma typically present with symptoms including headache, visual changes, nausea, and vomiting.[1316] Focal neurologic deficits are less common presenting signs. Hemorrhage can result in acute symptoms, leading to the diagnosis. Primary disease in the fourth ventricle[1317] or spinal cord has been reported in children.[1318]

Imaging and Histology

The typical MRI appearance of central neurocytoma is that of a well-circumscribed lobulated mass in the anterior portion of the lateral ventricles, making it difficult to distinguish from other intraventricular neoplasms such as ependymomas, astrocytomas, and oligodendrogliomas. Tumors often have an isointense or slightly hypointense signal relative to the cerebral cortex on T1-weighted images and a hyperintense signal on T2-weighted images with enhancement upon administration of gadolinium (Fig. 57-45).[1319-1321] Proton MRS and DWI have recently been described as a possible diagnostic tool in central neurocytoma.[1322] A characteristic MRS appearance of a high choline peak, a low NAA peak, and a glycine peak at 3.55 ppm is seen in a subset of patients.[1323,1324]

Histopathologic analysis of neurocytomas often reveals benign-appearing tissue composed of uniform round cells. Neurocytomas are classified as WHO grade II.[1325] Features such as large fibrillary areas, calcifications, and perivascular pseudorosettes are commonly observed.[1326] Routine hematoxylin and eosin staining of a neurocytoma can reveal the presence of cells with perinuclear halos suggestive of oligodendroglioma. However the reactivity with immunohistochemical staining for neuronal markers such as synaptophysin, βIII-tubulin, neural cell adhesion molecule, and NSE helps establish the diagnosis of a neurocytoma.[1327] As noted earlier atypical forms with mitoses, necrosis, and endothelial proliferation have been reported.[1328,1329] In tumors lacking synaptophysin or Neu-N staining, electron microscopy can assist in confirming the diagnosis.[1330] An MIB1 labeling index is useful for prognostic purposes. Patients with an MIB1 labeling index greater than 2% to 3% are referred to as having atypical neurocytoma and have a worse prognosis for local control and survival.[1309,1310,1328,1329] Subtotal resection, atypical histologic features, and older patient age have been associated with an increased risk of recurrence.[1331,1332]

Management

GTR can be curative for central neurocytomas and is the treatment of choice for pediatric patients.[1333,1334] A review of 73 children younger than 18 years pooled from multiple studies has shown an OS of 100% at 10 years for children who underwent a GTR.[1335,1336] Local failure was demonstrated in approximately 15% of patients who underwent complete resection alone versus 0% in patients who underwent complete resection with adjuvant radiation therapy. However given the absence of survival

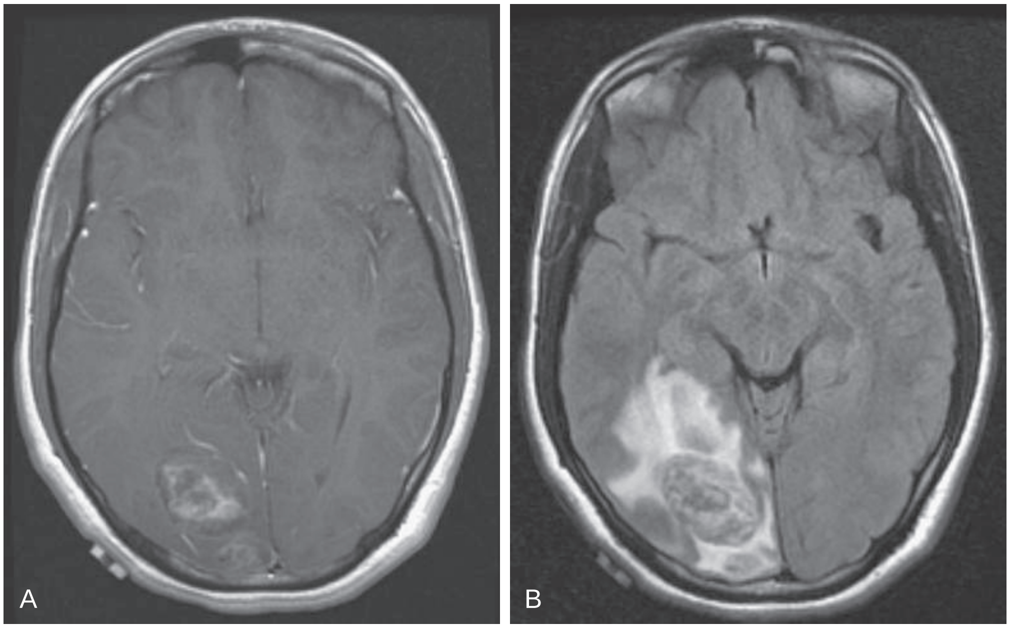

Figure 57-45 Right occipital extraventricular neurocytoma. **A,** An axial T1-weighted image with use of contrast material. **B,** An axial fluid-attenuated inversion recovery image. This tumor is an isointense to hyperintense extraventricular neurocytoma with surrounding edema.

difference and the potential neurocognitive toxicities, adjuvant radiation therapy is not recommended as initial treatment.[1312] Children with incomplete resections have a significantly higher risk of recurrence (mean, 100 months) and a lower OS (82%). Adjuvant radiation therapy has been shown to reduce the risk of recurrence but not the risk of death.[1312] In the case of incomplete resection, radiotherapy may be beneficial at a dose of 5400 cGy,[1337] although it should be noted that the number of patients available for evaluation in these studies is small. Radiotherapy should be more seriously considered for atypical neurocytomas, such as those with a high MIB1 labeling index (higher than 3%). A recent meta-analysis has shown that patients with lesions that have an MIB1 labeling index less than 3% have less than a 15% risk of recurrence and a 95% 5-year OS, compared with 38% and 66%, respectively, for patients with tumors that have an MIB1 labeling index higher than 3%.[1309,1310] In a review of 85 adult and pediatric patients, Rades and colleagues[1338] have demonstrated a marked difference in 5-year survival for incompletely resected atypical neurocytoma (43%). The addition of adjuvant radiation therapy increased 5-year survival rates to 78%. Complete resection was again found to be the best treatment, with 5-year survival rates of 93%. Adjuvant radiotherapy held no additional benefit in cases of completely resected atypical neurocytomas. Stereotactic radiosurgery has been explored as a potential first-line treatment for neurocytoma, but only in limited numbers of adult and pediatric patients,[1339] and it requires careful attention to the radiation therapy margins.[1340] Historically the use of chemotherapy for central neurocytoma has been limited, with only case reports and small case series being reported.[1341] Brandes and associates[1342] have described three adult patients with progressive neurocytoma treated with etoposide, cisplatin, and cyclophosphamide, which led to disease stabilization in two patients and complete remission in one patient.

Prognosis

Complete surgical resection and an MIB1 labeling index of less than 2% are the most important prognostic markers.[1309] Even with extraventricular location and atypical features, most patients will be long-term survivors. Thus judicious use of therapeutic modalities that can lead to significant long-term morbidity, such as radiation therapy, is indicated.

Choroid Plexus Tumors

Choroid plexus tumors usually arise from the epithelium of the choroid plexus in the lateral or fourth ventricles, where the choroid plexus is found. Although choroid plexus lesions represent only 3% of pediatric brain tumors, they comprise 10% to 20% of tumors that develop in the first year of life and account for a considerable percentage of in utero diagnoses.[1343] The median age at diagnosis for choroid plexus tumors is younger than ten years.[1344] Three histologic choroid plexus variants have been described: papillomas, atypical papillomas, and carcinomas.[1345] CPPs outnumber CPCs by a ratio of at least 5:1. Both tumors typically arise in the lateral ventricles in 50% of cases and in the fourth ventricle in 40% of cases. Tumors arising from multiple ventricles represent only 5% of cases. Because of their rarity, little is known about the molecular abnormalities that give rise to these tumors,[1346] although their strong association with the Li-Fraumeni p53 cancer susceptibility gene is well established.[1347] A significant percentage of choroid tumors will have abnormalities on array comparative genomic hybridization analysis.[889] The presence of normal *SMARCB1* staining in these tumors can be used to exclude ATRTs, which share many histologic features with choroid plexus tumors.[1221]

Little is known at present about the developmental or molecular biology of choroid plexus tumors, although a number of markers have been identified using gene array analysis.[1348,1349] Recent findings have implicated the transcription factor, TWIST1, notch3 signaling pathway, and tumor necrosis factor–related apoptosis-inducing ligand.[1350,1351] Patients with Li-Fraumeni syndrome who have a germline mutation of p53 are at increased risk for CPCs.[1347] Epigenetic analysis looking at DNA methylation patterns has shown increased methylation in CPC.[1352] DNA sequences from sporadic papillomas may harbor the human neurotropic JC virus.[916] The role of SV40 (another polyomavirus) in the development of pediatric CNS tumors, particularly ependymomas and choroid plexus, is an interesting one. SV40 sequences have been found in the tumor tissue of up to 50% of patients but not in adjacent areas of normal brain. SV40 is known to induce brain tumors in preclinical models, and SV40 can transform human cells in vitro, which may support a causative role for this polyomavirus in choroid plexus tumors.[917] Polio vaccines used in certain countries in the 1950s and 1960s were contaminated with SV40. In countries that have used uncontaminated vaccines, the identification of SV40 sequences in choroid plexus tumors is rare. However the incidence of choroid plexus tumors is similar between the two populations and thus appears independent of both SV40 exposure and SV40 detection within the tumors.[919,1353] Because of the strong association of Li-Fraumeni syndrome and *p53* mutations with CPC, patients need a comprehensive family history to ascertain the incidence of associated cancers and assist in the screening of family members. The presence of a *p53* germline mutation may affect the choice of radiation therapy as a therapeutic option and would indicate the need for genetic counseling in other family members.[1347] Additional mutations in the *TP53* gene have been discovered that lead to an increased incidence of CPC and can have an impact on the survival of patients with choroid plexus tumors.[1354-1356] The presence of PDGFR expression in a high percentage of cases (87%) is a rationale for the use of targeted inhibitors of this pathway in the context of a clinical trial.[1357]

Clinical Presentation

Initial symptoms are usually secondary to elevated ICP and hydrocephalus and include headaches, nausea, and vomiting, with papilledema. Other possible manifestations include lethargy, seizures, and failure to thrive. Because these tumors tend to arise in infants who retain

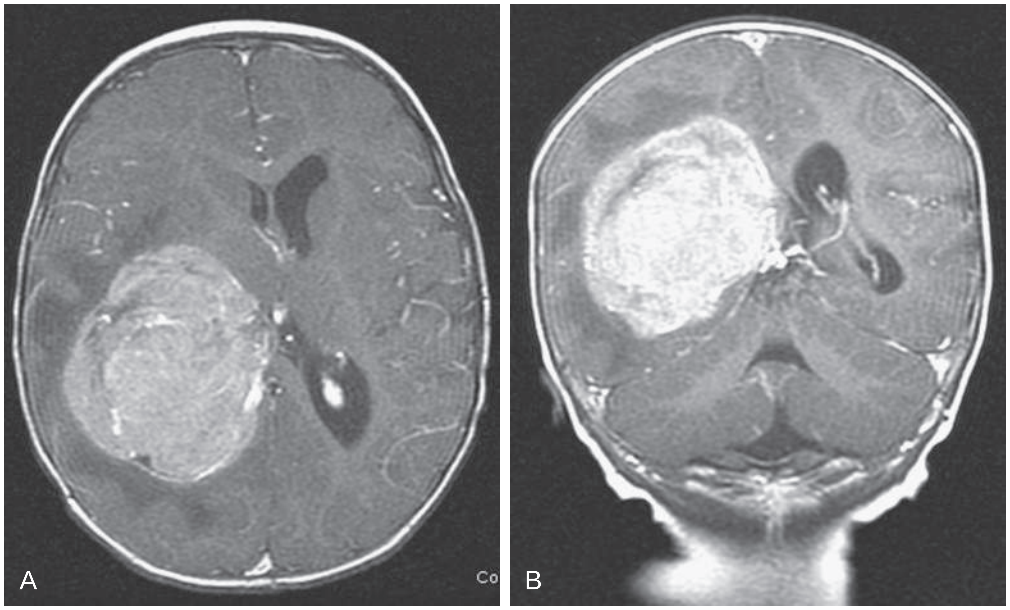

Figure 57-46 Choroid plexus carcinoma. **A,** An axial T1-weighted image with use of contrast material. **B,** A sagittal T1-weighted image with use of contrast material.

open sutures, the presentation may be relatively delayed, and the tumors may reach an exceptional size. Infants typically demonstrate irritability, lethargy, vomiting, a tense fontanelle, and macrocephaly, with splayed sutures. Although most choroid plexus tumors arise in the lateral ventricles, predominantly in infants, fourth ventricular choroid plexus tumors occur in persons of all ages, including adults. Metastatic disease can occur in CPPs, although these patients still have a good prognosis and many of the tumors will not progress. Leptomeningeal dissemination is common with CPCs and is a poor prognostic marker because of the limited use of craniospinal radiation therapy in this very young population. Dissemination through a VP shunt has been reported.[1358]

Imaging and Histology

A choroid plexus tumor should be suspected when a large enhancing tumor in the lateral ventricle is visualized on gadolinium-enhanced MRI (Fig. 57-46). Multilobular, calcified, well-delineated contrast-enhancing intraventricular masses are characteristic of choroid plexus tumors. Tumors are usually isodense on T1-weighted images and bright on T2-weighted images.[1359] CPCs often have more heterogeneous enhancement and edema signal on FLAIR than is routinely seen with CPPs.[1360] Unique characteristics of MRS can differentiate CPP from CPC at diagnosis although, for most patients, this differentiation will not obviate the need for surgery because of the high incidence of CSF flow obstruction in these patients, necessitating neurosurgical intervention.[1361]

CPPs (WHO grade I) have the lowest proliferative rate and are composed of fibrovascular fronds covered by a single layer of epithelial cells. They closely resemble the normal choroid plexus. Cytokeratin, S-100 protein, podoplanin, and vimentin are typically expressed on immunohistochemistry. GFAP, which is typically not seen in the normal choroid plexus, is found in approximately 25% to 50% of CPPs. In rare cases CPPs can transform into CPCs.[1362] In contrast CPCs (WHO grade III) manifest higher cell density, nuclear pleomorphism, frequent mitoses (more than 5 of 10 high-power fields), high nuclear-to-cytoplasmic ratios, necrosis, and invasive appearance (i.e., blurring of the papillary structures). Up to 20% of CPCs can be positive for GFAP.[1363] Atypical CPPs (WHO grade II) refer to cases in which a CPP has increased mitotic activity. Clear diagnostic criteria for these atypical tumors have not been established. These tumors can possess greater pleomorphism, increased cellularity, and areas of necrosis, but these elements are not required for diagnosis. However it appears that the presence of mitotic activity (2 mitoses or more per 10 high-power fields) is the sole atypical histologic feature independently associated with recurrence.[1363] Atypical CPPs accounted for approximately 15% of all CPPs in one large series.[1363]

Management

After diagnostic neuroimaging studies, high-dose corticosteroids are often administered when elevated ICP or tumor edema is suspected. Because the extent of surgical resection is the single most important factor that determines the prognosis in choroid plexus tumors, the goal of the neurosurgeon is to perform a GTR.[1364] In patients with CPP, complete resection is usually sufficient therapy.[1365] Achieving complete resection may require more than one surgical procedure but appears to improve outcome.[1366] One obstacle to the surgical removal of choroid plexus tumors is the rich vascular network that is often located within the tumor. The choroid plexus receives its blood supply from the anterior and posterior choroidal arteries, branches of the internal carotid artery, and the posterior cerebral artery. Achieving a GTR in cases of CPP and atypical papilloma is often curative, and adjuvant therapy may be deferred after normal results of a restaging evaluation are found.

Because most children diagnosed with CPC are younger than 3 years, chemotherapy is the treatment of choice in those for whom a complete resection cannot be achieved.[1194,1344] Various multiagent chemotherapy regimens have been explored, and preliminary evidence suggests that CPCs are chemosensitive tumors. Currently an International Society for Pediatric Oncology protocol exists that is exploring different chemotherapeutic options. Agents such as carboplatin and etoposide have shown good activity. In addition, intrathecal therapy has been incorporated into treatment with ara-C and etoposide. The role of radiotherapy is controversial and is usually reserved for children older than 3 years who have had a subtotal resection, malignant features within the tumor, or dissemination of the tumor along the neuraxis.

Prognosis

GTR is often curative for CPP. Even in patients with a subtotal resection, 50% of the residual tumor will not demonstrate progression.[1367] The 5- and 10-year PFS and OS rate for patients with papillomas are 81% and 77%, respectively, versus 41% and 35%, respectively, for persons with carcinomas.[1344] Atypical CPP can recur, and thus careful follow-up is needed. The long-term prognosis for this group of patients remains excellent.[1363] Patients with dissemination at diagnosis do less well. Several adjuvant platinum-based chemotherapy regimens have been used with some measure of success,[1368] but at present no standard protocol has been established for CPC. Development of an international protocol for the prospective treatment and outcome of choroid papilloma, atypical CPP, and CPC is under way.

Germ Cell Tumors

CNS GCTs are the most prevalent tumors of the pineal region and represent approximately 3% to 5% of intracranial childhood malignances in the United States. These tumors are much more common in Asia, particularly in Japan.[1369,1370] The reason for this geographic variability is unknown. Most GCTs occur in early adolescence, and males are affected significantly more often than are females.[1371] Males are much more likely to have both pineal and suprasellar GCTs, with a reported male to female ratio of approximately 14 : 1.[1372] Germinomas are much more common than nongerminomas.[1373] Histologically these tumors resemble the GCTs that arise in the gonads.

Most (95%) GCTs arise in midline sites such as the infundibular region (40%) and pineal region (50%), although 5% arise simultaneously in both regions without an apparent connection.[1374] Occasionally they are isolated to the basal ganglia[1375] but can be approached in a similar fashion to those in the pineal or suprasellar area.[1376] CNS GCTs are presumed to result from the abnormal migration of primitive germ cells early in embryogenesis within the gonadal ridge.[1377,1378] Occasionally metachronous lesions at both sites are detected at the time of diagnosis.[1377,1379] CNS GCTs are divided into two clinical groups, which reflect sensitivity to cytotoxic therapies—pure germinomas (60%) and NGGCTs (40%).[1369,1380] NGGCTs include yolk sac tumors (endodermal sinus tumors), embryonal carcinomas, choriocarcinomas, immature teratomas, teratomas with malignant transformation, and mixed GCTs. Mixed GCTs are defined as tumors that contain any two of the elements previously listed and can include mixtures of germinoma and nongerminoma. Germinomas are the most common GCT of the pineal region,[1372] although NGGCTs and germinomas arise with equal frequency in the suprasellar region. A male predominance occurs in pineal region tumors, although both genders are equally affected by tumors in the suprasellar region. Mature teratomas of the brain causing significant mass effect have been reported.[1381] Their peak age of occurrence is in the second and third decade of life.

No clear genetic predisposition to CNS GCTs has been identified other than males with Klinefelter syndrome (47XXY).[1382] Of interest a number of CNS GCTs have an abnormal karyotype, including gain of chromosome X, which raises the possibility that patients with Klinefelter syndrome are uniquely at risk because of the presence of their additional X chromosome. A number of cases of GCTs in patients with Down syndrome have also been reported.[1383,1384]

Clinical Presentation

The clinical presentation between suprasellar and pineal region GCTs can differ. Patients diagnosed with suprasellar GCTs often have a long prodrome, often several years in duration.[1385] The earliest symptoms usually involve endocrine dysfunction, most frequently symptoms of diabetes insipidus (DI).[1386] This presenting symptom can also be observed in other lesions of the pituitary region, such as lymphocytic hypophysitis.[1387] In some patients with DI, a mass is not identified on MRI scan but over time a mass becomes evident, leading to the diagnosis. Eventually other endocrine manifestations may occur, such as growth impairment, delayed puberty, and hypothyroidism. Visual loss and symptoms of raised ICP are late manifestations when the tumor has reached appreciable size or spread in a periventricular distribution. Even in patients without MRI evidence of pituitary or hypothalamic involvement of tumor, endoscopic evaluation can often detect subtle areas of tumor.[1388] It is not yet clear whether patients with endoscopically identified regional disease should be considered to have metastatic disease.

Tumors arising in the pineal region often produce headache, nausea, and vomiting because of obstructive hydrocephalus. Limitation of vertical gaze, convergence nystagmus, impaired pupillary reflexes, and double vision may occur because of tectal compression (Parinaud syndrome). Atypical presentations occur when GCTs arise in unusual locations such as the basal ganglia, when they present with widespread leptomeningeal metastases, or when they diffusely infiltrate deep white matter structures.

GCTs can cause precocious puberty because of release of β-human chorionic gonadotropin (β-HCG).[1389,1390] Atypical presentations, such as movement disorders or

depression as the presenting symptom, can result in significant delays in diagnosis.[113,1385]

Imaging and Histology

GCTs can have a heterogeneous appearance on CT and MRI and can differ between the pineal and suprasellar regions.[1391] Most are contrast-enhancing solid lesions, with isointense signal on T1-weighted sequences and a bright signal on T2-weighted sequences (Fig. 57-47).[1392] Cysts are commonly observed, especially in nongerminomas.[1393] These signal characteristics overlap with other common tumors of the pineal region and require biopsy or hormone marker analysis for accurate diagnosis.[1380,1394] An important exception is CNS teratoma. These lesions are composed of all three mature tissue elements and therefore will demonstrate calcified areas with adjacent cysts and low-density regions of fat. Areas of bright signal on T1-weighted images, consistent with hemorrhage, are suggestive of choriocarcinoma.[1393]

The NGGCTs are unique among CNS tumors in that they can be diagnosed solely on the basis of expression of tumor markers.[1395,1396] Either β-HCG, a normal product of syncytiotrophoblasts, α-fetoprotein (AFP), a normal product of yolk sac endoderm, or both can be detected in the blood and CSF of patients with NGGCTs. β-HCG is associated with choriocarcinoma, although low levels can also be associated with germinomas. CSF levels tend to be higher than levels in the serum.[1397] AFP is expressed by yolk sac tumors, although low immunohistochemical expression can be observed in some teratomas. Although placental alkaline phosphatase (PLAP) and lactate dehydrogenase isoenzymes and CSF c-kit have been used as markers of germinoma,[1395,1398-1400] immunohistochemical staining for these markers is more commonly used for diagnosis. Because AFP is normally expressed in newborns, considerable attention must be given to interpretation of these levels in infants.[1401]

The histologic identification of CNS GCTs is critical for proper therapeutic assignment and prognostic counseling. Seven major categories are recognized by the WHO.[1402] Clinically mixed GCTs are encountered in most patients, except those with pure germinomas or mature teratomas, and the most malignant component typically dictates the type and intensity of the therapy.

Germinoma is the most common CNS GCT encountered and is considered the equivalent of the testicular seminoma. The appearance of these large cells on hematoxylin and eosin staining, frequent mitoses, and lymphocytic infiltrates is characteristic and can easily be observed on smear preparations. Cells stain brightly for both c-kit and octamer-4.[1403,1404] Placental alkaline phosphatase has been less reliable. SALL4 has been studied as a novel marker and appears sensitive in the diagnosis of CNS GCT.[1405] Even pure germinomas can possess syncytiotrophoblastic giant cells, resulting in low-level expression of β-HCG, which does not upstage their classification to the more malignant choriocarcinoma.[1390]

NGGCT is typically used to refer to one of three different malignant germ cell tumor variants, as well as teratomatous elements with atypical or malignant degeneration. The first, yolk sac tumor (endodermal sinus tumor), is an epithelial tumor that can mimic the appearance of germinomas but highly expresses AFP throughout the cytoplasm. Embryonal carcinoma is an epithelial-derived tumor that has a characteristic appearance with abundant mitoses and diffuse presence of cytokeratin. This latter feature can help differentiate these tumors from germinomas because both can express PLAP and octamer-4. Lastly, choriocarcinoma is a trophoblastic tumor of extraembryonic origin. It requires the identification of cytotrophoblastic elements and syncytiotrophoblastic giant cells. Hemorrhagic necrosis is a common feature of this tumor, and the giant cells stain brightly for β-HCG.

Teratoma refers to a group of three lesions that have evidence of differentiation along the three embryonic germ cell layers—ectoderm, endoderm, and mesoderm:

1. Mature teratoma possesses fully differentiated tissue elements of all three layers. The ectodermal components often contain skin, brain, and/or choroid plexus. The mesodermal component can frequently include cartilage, bone, fat, and/or

muscle, although the endodermal component often contains respiratory or gastrointestinal cysts lined by epithelium. Teratomas usually have an absent or low mitotic index.

2. Immature teratoma is similar to mature teratoma but possesses some elements from one or more of the germ cell layers that are not fully differentiated. Most commonly seen are mitotically active stromal elements or neuroectodermal cells. These immature elements are at considerable risk for malignant degeneration and thus require additional therapy unless a complete resection has been performed.[1406]
3. Teratomas with malignant transformation are rare lesions in which an area of malignant cells of any histologic type is observed. Rhabdomyosarcoma or undifferentiated sarcoma is the most commonly seen, although almost any tumor can occur in the context of teratomas because teratomas already possess all three germ cell layers.[1407]

The diagnosis of an intracranial GCT is suspected in any patient with acquired DI or Parinaud syndrome. Although the location of the primary tumor on neuroimaging studies and certain features of the clinical presentation are supportive of the diagnosis of a CNS GCT, the diagnosis must be confirmed by histology or CSF tumor markers (Table 57-7). Patients with a thickened pituitary stalk with DI are more likely to have an infiltrative tumor process than Langerhans cell histiocytosis or hypophysitis, and the appropriate workup should be initiated.[1408] Histologic confirmation may not be necessary in patients with elevated serum and/or CSF concentrations of tumor markers (AFP or β-HCG) consistent with an NGGCT.[1395,1396]

The tumor markers β-HCG and AFP are useful in not only confirming the presence of a CNS GCT but also in monitoring response to therapy and in suspecting earlier recurrence. Elevation of AFP alone suggests yolk sac (endodermal sinus tumor), whereas a high level of β-HCG suggests choriocarcinoma. Pure germinomas may have modest elevations of CSF β-HCG, usually lower than 50 mIU/mL (100 mIU/mL at some institutions). Lactate dehydrogenase isoenzymes, the soluble c-kit oncogene product, and PLAP are also detectable in the CSF of patients with a germinoma.[1395,1399,1400] Serum markers of β-HCG at diagnosis can be negative, even in the presence of significantly elevated CSF levels, demonstrating the importance of a comprehensive workup for this patient population, including MRI of the spine and CSF for markers and cytology.[1395,1409] Proper prospective studies using ventricular CSF rather than lumbar CSF have not been completed and therefore should not be used for staging at present.[1116]

Management

Preoperative evaluation should include contrast-enhanced brain and spine MRI, serum and CSF tumor markers (if lumbar puncture can be safely performed), CSF cytology, assessment of endocrine function and visual acuity, and visual field examinations for suprasellar disease. In the absence of elevated lumbar CSF tumor markers, a biopsy should be performed. Aggressive resection leading to morbidity is neither necessary nor advisable in cases of germinoma because of the tumor's exquisite sensitivity to cytotoxic and radiation therapies. Thus less invasive neurosurgical procedures to obtain a tissue sample, such as an endoscopic or stereotactic biopsy, are used more frequently.[1174,1388,1410] A third ventriculostomy is frequently performed at the same time as an endoscopic biopsy in patients with noncommunicating hydrocephalus and a pineal region tumor.[1411] Radical resections of an NGGCT may be easier to accomplish after several courses of chemotherapy.[1412]

Patients with germinomas have a number of nonsurgical treatment options.[1413,1414] With radiation therapy alone for pure germinoma, the 5-year OS rate has approached 90% to 95% in clinical series[1415]; however, radiation therapy alone is inadequate for NGGCT, with 5-year OS ranging from 0% to 30%.[1416,1417] Several new treatment strategies are under investigation in an attempt to minimize some of the late effects of radiation therapy, as seen in long-term survivors of CNS germinomas.[1418] Administering an intermediate radiation dose of

approximately 4000 to 5000 cGy encompassing the brain and ventricles is curative treatment for most patients with localized intracranial germinomas. Craniospinal radiation therapy is no longer routinely used for this population. Although whole-brain radiotherapy (WBRT) has been used in the past, whole ventricular fields are now recommended to spare the outer margin of the cortex without increasing the risk of recurrence. Typically 3000 cGy is administered to the whole ventricular region and the primary tumor receives an additional 1500 cGy. This therapy is effective, with 10-year EFS in excess of 90% and distant recurrences such as spinal metastases rarely occurring.[1419] Concurrent pineal and pituitary tumor locations represent regional rather than metastatic disease and can also be adequately treated with whole ventricular radiation therapy.[1420] Like other patients with brain tumors receiving radiation therapy, these children often experience late consequences of radiation therapy, such as cognitive and endocrine deficiencies and radiation therapy–induced secondary tumors.[1418] This outcome has led to the development of treatment regimens using adjuvant chemotherapy followed by response-based radiotherapy to permit a selective reduction in dose (from 4500 to 3000 cGy) in patients whose tumors completely disappear after two to four courses of chemotherapy.[1421-1424] A similar approach has been used with success by the Japanese cooperative group, including an intermediate-risk group of germinomas with elevated β-HCG.[1425] Decreasing the volume from whole ventricle to involved field is not sufficient because a number of failures have been noted with this approach.[1426,1427] The optimal dose and field of radiation and the best combination of chemotherapy are still being investigated and will require further follow-up to confirm efficacy and decreased toxicity. Proton radiation therapy is favored over photon therapy when it is available because efficacy seems equivalent but potential toxicity may be reduced.[1428] In one study attempts at treating patients with chemotherapy alone have demonstrated significant responses but a recurrence rate of approximately 50%.[1429,1430] Although these patients had an excellent salvage rate with radiation therapy, a higher craniospinal dose of 3600 cGy is then required. For this reason chemotherapy alone is not used for germinomas outside of formal clinical trials.

Relapse germinoma is rare, but patients who have a relapse may still respond well to treatment, including additional radiation, chemotherapy, and high-dose chemotherapy with autologous transplant.[356,1431]

For patients with NGGCT, more aggressive chemotherapy, radical tumor resection, and high-dose and high-volume radiotherapy are required for survival.[1421,1432-1435] NGGCTs are highly responsive to chemotherapy, as was seen in one study with 16 of 17 patients achieving a CR or PR with two cycles of cisplatin and cyclophosphamide-based therapy, one third of whom were long-term survivors.[1432] The use of consolidation with high-dose chemotherapy and stem cell rescue is being developed in patients with residual disease[348] and appeared to further improve outcome in a small pilot series.[1436] It is not clear if patients with focal NGGCT require CSI, and this question is currently being evaluated in a large prospective cooperative group trial. Many patients initially treated with chemotherapy who have progressive disease can undergo salvage therapy with high-dose chemotherapy and craniospinal radiation therapy.[1437] Immature teratomas are classified as NGGCTs but can often be treated with a more conservative approach. A complete resection may be sufficient therapy, and the prognosis is good. Patients with incomplete resection likely require adjuvant therapy.[1406]

After treatment GCTs can demonstrate significant progressive growth on an MRI scan with concurrent clinical decline in the setting of normal tumor markers (β-HCG and/or AFP). Although a nonsecreting germ cell recurrence cannot be excluded, most of these cases represent growing teratoma syndrome.[1438,1439] These lesions are nonmalignant progression of the teratomatous component of lesions that, when resected, will relieve the clinical symptoms.[1438,1440] Patients with growing teratomatous syndrome are not considered to have progressive disease, in spite of the dramatic increase in the size of the lesion on MRI. Neither radiation therapy nor chemotherapy should be discontinued in these patients.

Prognosis

Patients with germinoma have an excellent prognosis because of the tumor's sensitivity to radiation and chemotherapy. For these patients the major treatment challenge is maximizing the quality of life and limiting long-term sequelae of therapy. The COG is currently conducting a randomized phase III study comparing standard radiation therapy alone versus chemotherapy followed by response-dependent reduced-intensity radiation therapy, in which the primary outcome measures are PFS, OS, and quality of life. For patients with germinoma who progress after radiation therapy, many can undergo salvage therapy with high-dose chemotherapy, with or without stem cell transplantation, followed by a higher dose and volume of radiation therapy.[1441,1442] Chemotherapy and radiation therapy for patients not previously treated with radiation therapy can also lead to a high salvage rate.[1437]

Nongerminomas have a less favorable prognosis and thus clinical trials are evaluating conventional multiagent chemotherapy followed by dose-intensive myeloablative chemotherapy and second-look surgery for poor responders, followed by high-dose craniospinal radiation therapy. A small fraction of these patients will respond to high-dose chemotherapy and stem cell rescue,[1442] and long-term survival will improve, particularly if they can be brought back to a state of minimal residual disease.[1443] The response rate of recurrent NGGCT to second-line chemotherapy is poor. Poor prognostic factors in NGGCTs include degree of resection, presence of hemorrhage, and metastases.[1444] A rise in CSF β-HCG can be a sensitive marker of pending relapse and was identified well in advance of elevated levels in the serum.[1397]

Craniopharyngiomas

Craniopharyngiomas are benign nonglial tumors in children and account for 3% to 5% of all pediatric brain tumors, with a peak age ranging between 6 and 14 years.

These tumors arise from Rathke pouch epithelium and are classified as WHO grade I tumors.[1445] Craniopharyngiomas are slow-growing tumors that arise in the sella and parasellar regions; they are composed of both solid and cystic components, which often extend into the parasellar cisterns and occasionally invade adjacent cortical and vascular structures.[1446] Calcification is a common finding of these lesions,[1447] although it is not pathognomonic for these tumors. Compression of critical intracranial structures can lead to pituitary, hypothalamic, and optic dysfunction. As a result these patients often have complicated medical courses and long-term sequelae. Nigerian and Japanese children appear to have a greater risk for these tumors.[1370,1448] A strong association between β-catenin mutations and adamantinomatous craniopharyngioma has been identified.[1449,1450]

Clinical Presentation

The typical onset of craniopharyngioma is insidious and can extend over several years. The diagnosis is often made in retrospect upon recognizing one or more slowly evolving symptoms, such as progressive visual loss, delay in sexual maturation, growth failure, weight gain, and DI.[1451] Eventually clinical recognition is heralded by a change in mental status as enlargement of the cystic component causes obstructive hydrocephalus. More than 70% of children have growth hormone deficiency, obstructive hydrocephalus, short-term memory deficits, and/or psychomotor slowing at the time of diagnosis. The presenting feature in young adults also includes other symptoms of hypopituitarism, such as galactorrhea or amenorrhea in females and impotence in males. The differential diagnosis of a suspected craniopharyngioma is limited because of the characteristic radiographic findings of these lesions.[1452] Congenital craniopharyngioma associated with a paraneoplastic expression of parathyroid hormone–related protein expression has been reported.[1453]

Imaging and Histology

MRI features (Fig. 57-48) usually include a multicystic and solid enhancing suprasellar mass.[1454] The T1-weighted signal is usually isointense. The chiasm is often stretched over the suprasellar mass and, if dorsal extension is sufficient, hydrocephalus will be apparent.[1455] A classic neuroimaging distinction of craniopharyngiomas from other suprasellar tumors such as a diencephalic glioma or GCT is the presence of calcifications on a noncontrast CT scan. With use of contrast material, the solid components of craniopharyngiomas are usually bright on CT. Transcranial Doppler can also be used in the diagnosis and surveillance of these tumors.[1456]

Histologically craniopharyngiomas are divided into adamantinomatous and papillary subtypes. Adamantinomatous craniopharyngiomas are the more common variant in adults and children and typically consist of cystic and solid areas, with frequent calcifications. Papillary tumors, which are seen almost exclusively in adults, are predominantly solid, without calcification, and are less infiltrative. The cysts seen in craniopharyngioma usually contain a dark liquid with the consistency of machine oil. The diagnosis of adamantinomatous craniopharyngioma requires the presence of squamous epithelium bordered by palisading columnar epithelium.[1445] Gliosis and Rosenthal fibers can be observed but rarely result in misdiagnosis because of the other characteristic features of craniopharyngioma. Palisading columnar cells can have a high MIB1 labeling index rate ranging from 0% to 15%, but this finding does not correlate with a poorer outcome than for patients with a low MIB1 labeling index rate.[1457,1458]

Management

Surgical resection remains the standard approach for craniopharyngioma in many centers, both through an

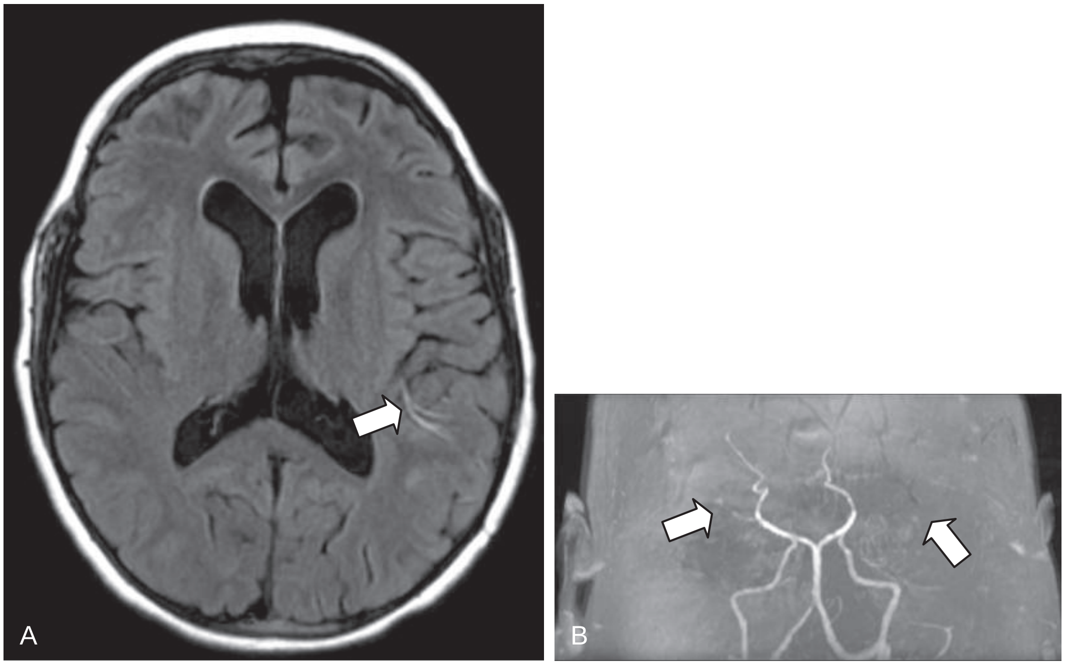

Figure 57-49 Radiation-induced moyamoya disease. **A,** An axial fluid-attenuated inversion recovery image showing the "IVY" sign of slow flow *(arrow)*. **B,** Coronal reconstruction from a maximal intensity projection image from magnetic resonance angiography demonstrating missing lateral vessels *(arrows)*.

open approach and via an endoscopic endonasal approach.[1452,1459,1460] When the child presents with acute raised ICP, the initial management will relate to measures to alleviate this condition with high-dose corticosteroids and monitoring in the intensive care unit. Because patients may have unappreciated panhypopituitarism, baseline hormonal and electrolyte levels should be obtained and the child should be given empiric stress-dose steroids.

Although it is somewhat controversial, a complete microsurgical resection of the entire tumor is the treatment of choice for newly diagnosed craniopharyngiomas.[1461] A multistaged operative approach may be planned, including a combination of transsphenoidal, pterional, and transcallosal approaches, depending on the extent and location of the tumor. Many tumors are adherent to adjacent structures, which will either limit the degree of resection or result in potentially significant postsurgical morbidity.[1446]

Despite the surgical accessibility of many of these tumors, radical resection does not guarantee recurrence-free survival, and the 3-year EFS after a GTR is 60%.[1462] Aggressive resection can result in more extensive hypothalamic deficiencies and visual complications,[1459,1463] even in patients without evidence of hypothalamic involvement at diagnosis.[1464] Careful management of DI can be required immediately after surgical resection in these patients,[1465] which may lead to a permanent condition. Postoperative behavioral sequelae include altered regulation of appetite and weight control, impulsivity, hypersexuality, and changes in memory.

An alternative treatment strategy for the long-term control of craniopharyngiomas is subtotal resection[1466] followed by high-dose radiotherapy of the involved field.[1467-1469] Whether this approach is superior in terms of tumor control and preservation of quality of life remains to be established, but several studies have reported comparable or even improved PFS and OS statistics in retrospective, uncontrolled institutional series.[1462,1470-1473] In patients with recurrent craniopharyngioma, an attempt at a complete resection can be considered, although the need for focal radiation therapy will be required for most of these patients. Proton therapy, based on the lack of an exit dose, is considered the preferred method of radiation therapy if it is available locally.[1474,1475] Long-term complications of radiation therapy include secondary malignancies, optic neuropathy, and vascular injury leading, rarely, to moyamoya disease (Fig. 57-49).[85,1476-1478] The recent identification of the BRAF V600E activating mutation in almost all papillary craniopharyngiomas, which are usually seen in adults,[1479] offers this patient population the option of targeted therapy.[1480] The adamantinomatous subtype, which is found predominantly in children and is characterized by mutations in B-catenin, will need to await development of improved inhibitors of this pathway.

A temporizing approach to control the cystic components of the tumor is the intracystic instillation of sclerosing agents such as bleomycin or phosphorus-32.[1481-1483] The use of intralesional bleomycin has also been shown to help delay the need for aggressive surgery or radiation therapy, although prospective clinical trials of this approach are needed.[1484] This procedure has the risk of leakage of the bleomycin from the cyst into adjacent brain tissue and should be reserved for patients for whom all other management approaches have failed.[1485] However the solid tumor usually continues to grow and make new cysts, thus making subsequent resections more difficult. In addition subsequent external beam radiotherapy treatment planning may be difficult because of the unpredictable dosimetry of ^{32}P.[1482] Recently pegylated interferon alpha 2b has been used to stabilize cystic progression in patients with craniopharygioma.[1486]

Recurrent or progressive craniopharyngiomas may be treated with surgery, radiosurgery, fractionated radiotherapy, or chemotherapy. Responses to chemotherapy have been reported with interferon, vinblastine, cisplatin, pegylated interferon,[1487] and other agents,[1471,1488-1493] although well-designed studies to test different agents for craniopharyngioma are lacking.[1494]

Prognosis

The most important factors that correlate with PFS are the extent of resection and postoperative radiation therapy. Larger tumors and those with cysts are more likely to recur.[1495] In a surgical series, recurrence or progression occurred in 7% to 15% of cases after total resection and in 50% of cases after subtotal resection.[1496] The recurrence rate of 15% is observed when subtotal resection is followed by radiation therapy.[1497] The outcomes between adult and pediatric patients does not appear to be different.[1498] Recurrences along the surgical tract have been reported but are thought to be related to the procedure rather than representing metastatic disease and are treated with surgery and focal irradiation, if needed.[1499] Unfortunately many long-term survivors experience significant morbidity related to panhypopituitarism,[1500] cognitive impairment, sleep pattern disturbance, and obesity.[1498,1501-1505] Growth hormone deficiency is present in 100% of patients,[1506] but the early use of growth hormone in these patients is not thought to be contraindicated.[1507,1508] Although narcolepsy is uncommon,[1509] control of weight and regulation of sleep can be difficult because their circadian rhythms are disrupted and melatonin production is severely diminished.[1510] The use of stimulants has been investigated, with preliminary positive results,[1511] although clear efficacy for these interventions is lacking.[1512-1514] Although still in the early stages, attempts to regulate obesity in these patients have also demonstrated some success.[1515] Finally, psychosocial problems can be significant in this patient population, and a comprehensive team approach is beneficial.[1516]

Infant Tumors

Infants and young children with brain tumors present specific therapeutic challenges because of the morbidity associated with current treatment strategies. As a group infants and young children with brain tumors have poor outcomes, with 5-year EFS and OS rates as low as 19% and 25%, respectively.[1517] This poor prognosis can be related to unique characteristics of the tumors in this age group, as well as the significant limitations with regard to therapy. Evidence from numerous sources has suggested that neural development extends from the embryonic period through adolescence and is especially prominent during the first 3 years of life, making young children most susceptible to neurotoxic insults.[1518] These findings are in keeping with early observations that the most devastating consequences of radiotherapy in children, in terms of neuropsychological sequelae, were greatest in children younger than 3 years.[1519] Although early observations have led to the arbitrary age limit of 3 years as the cutoff for introduction of radiation therapy, numerous subsequent studies have shown that even older children can experience cognitive, endocrine, behavioral, and many other medical problems after undergoing radiation therapy.[1520,1521] Consequently several strategies have emerged to delay or eliminate radiotherapy through the use of chemotherapy in an attempt to preserve cognitive, neurologic, and endocrine function in younger children.[1522,1523]

A significant proportion of pediatric brain tumors occur in infants and young children. Data from the Childhood Brain Tumor Registry of the United States from 2000 to 2004 have shown that approximately 28% of childhood brain tumors occur in children younger than 4 years[1524] and 18% of brain tumors occur in children younger than 2 years.[1525] Tumor location in infants and young children is different from that in the older child, with a predominance of supratentorial tumors.[1525-1527] Seventy percent of tumors that present in the first week of life are also located supratentorially[1528] compared with 56% for the pediatric population.[1529] The male to female ratio in this age group is also different in that there is a lower male predominance in this age group[1526] when compared with childhood brain tumors overall. Histopathologic subtypes in infants and young children are also different from those in the older child, but accurate determination of this difference has been difficult because early epidemiologic data collected by the traditional data collection agencies such as the SEER registry and National Brain Tumor Registry did not have standardized histologic subtype information. For example PNET was not previously recognized as a separate entity in the SEER Registry. In the large cooperative groups brain tumors were categorized differently, and thus the POG excluded medulloblastoma from PNET protocols, although the CCG routinely included medulloblastoma in PNET protocols.[1522] The distribution of tumor types treated in the infant POG clinical trial ("Baby POG") was medulloblastoma, followed by ependymoma, PNET, and malignant glioma.[1530] However in a review of 1289 patients aged younger than 1 year reported in the literature, astrocytoma was the most common diagnosis, comprising 31% of cases (of which 75% were low grade and 25% were reported as high grade), followed by medulloblastoma at 12%, ependymoma at 11%, choroid plexus tumors at 11%, sPNET at 7%, and teratoma at 5%.[1526] Astrocytoma and medulloblastoma remain the most common in the young age group, although a peak of ependymoma is seen within the first 2 years of life, along with an increased incidence of PNET.[1517] A recent analysis of the SEER database has revealed that the incidence of brain tumors in infants and young children has remained stable since 1986. The most common histologies in the dataset were glioma, medulloblastoma, and sPNET and ependymomas.[1531]

Two important histologic diagnoses in infants include teratomas and ATRTs, which account for 4.9% and

0.3%, respectively, of infant brain tumors.[1526] Briefly, ATRT is a rare tumor of childhood (see the earlier section on ATRT), which has only recently been recognized as a separate entity; 75% of these tumors carry a unique chromosome 22q11.2 cytogenetic abnormality.[1291] An initial description of malignant rhabdoid tumors of the kidney,[1532] followed by the description of the simultaneous appearance of renal and CNS tumors with similar histologic features,[1533] eventually resulted in the recognition that this unique histology represents a separate entity.[1257,1300] ATRT primarily affects young children at a mean age of 17 to 24.5 months, with 75% occurring in children younger than 3 years.

Clinical Presentation

The clinical presentation of brain tumors in infants and young children is most often associated with the symptoms of obstructive hydrocephalus, which in this age group manifests as persistent vomiting, irritability, lethargy, abnormal gait and coordination difficulties, failure to thrive, bulging and splayed fontanelles, seizures, and loss of developmental milestones. In a meta-analysis of 13 studies reported in the literature consisting of 332 children younger than 4 years presenting with intracranial tumors, increasing head circumference and macrocephaly was reported as the most common presentation (41%). Other presentations included focal motor weakness, head tilt, squint, abnormal eye movements, altered levels of consciousness, and hemiplegia.

Management

The historic approach to treating infants and young children with brain tumors had focused on the use of surgery and radiation. In the late 1960s serious functional and neurocognitive sequelae that were incompatible with a normal productive life, especially for children younger than 2 years, were recognized.[1519] As a result several different strategies to delay or exclude radiotherapy from the treatment of young children with brain tumors were developed and were centered on the use of chemotherapy.[1522,1523,1534,1535] van Eys and coworkers[1536] (1985) treated 12 young children with medulloblastoma using mechlorethamine, Oncovin (vincristine), procarbazine, and prednisone chemotherapy without radiotherapy and found that 8 of 12 patients were long-term survivors. This strategy led to other clinical trials, including those investigated by the POG, which worked on the premise of giving chemotherapy until the child achieved an age at which radiotherapy was accepted as less detrimental and its benefits could still be realized.[1522,1523] The "Baby POG" protocol, initiated in 1986, enrolled 198 children, 132 of whom were younger than 24 months, who were treated with chemotherapy for 2 years, and an additional 66 children between the ages of 24 and 36 months were enrolled, who received chemotherapy for 1 year prior to receiving radiotherapy.[1530] Chemotherapy consisted of two 28-day cycles of cyclophosphamide plus vincristine followed by one 28-day cycle of cisplatin and etoposide; these cycles were given for 1 or 2 years, depending on the age of the child at diagnosis or until there was disease progression, after which radiotherapy was administered. After two cycles of cyclophosphamide and vincristine, 39 of 109 evaluable patients showed a CR or PR, although patients with brainstem glioma and PNET did poorly. The PFS at 1 year for children diagnosed between the ages of 24 to 36 months and PFS at 2 years in children diagnosed at younger than 24 months were 41% and 39%, respectively. The 5-year PFS was reported as 30% ± 5%, and the 5-year OS was 39% ± 4%. The single most important predictor of survival was the degree of surgical resection, because children with a GTR had a 5-year OS of 62% ± 7% compared with those with a subtotal resection, whose 5-year survival was only 31% ± 5%. Of great importance in this landmark study was its demonstration that a small subset of children could achieve disease control without radiotherapy, and that even a delay of 1 or 2 years did not adversely affect outcome in all patients.[1522,1523,1534] Other study groups have adopted a similar approach of delaying radiotherapy through use of chemotherapy. The national CCG-9921 clinical trial for infants with medulloblastoma, CNS PNET, and ependymoma used upfront chemotherapy for 1 year followed by focal radiotherapy to the involved site or craniospinal radiotherapy.[1537] This was an "8-drugs-in-1-day" clinical trial that included 46 children with medulloblastoma who were younger than 18 months at the time of diagnosis, most of whom had gross total resections and were able to avoid radiotherapy; 22% were progression-free at 3 years.[1537] The German Pediatric Brain Tumor Study Group pilot tested an intensive chemotherapy regimen consisting of procarbazine, ifosfamide, cisplatin, cytarabine, vincristine, and high-dose methotrexate for children to delay or avoid radiotherapy (trial HIT-SKK87). A direct comparison to the results of Baby POG cannot be made because the results of HIT-SKK87 have not yet been published. The United Kingdom Children's Cancer Study Group piloted a Baby Brain protocol in 1989 using weekly alternating cycles of myelosuppressive and nonmyelosuppressive chemotherapy consisting of vincristine and carboplatin, vincristine and methotrexate, vincristine and cyclophosphamide, and cisplatin to delay or avoid radiotherapy. Although only 28 children were treated with the protocol, the 4-year OS was 35%.[1538]

The overall results of these "Baby" chemotherapy protocols were thus somewhat disappointing, with EFS rates of 20% to 40%, although the ability to defer radiation therapy in this patient population was an important advance. Given the high response rate for infants treated according to these protocols, strategies centered on high-dose chemotherapy with ASCR were developed to improve the response rates already being observed.[728,1535] The French Society of Pediatric Oncology used this approach of high-dose chemotherapy with autologous bone marrow rescue (ABMR) in their BBSFOP protocol in an attempt to extend survival of young children with relapsed or progressive disease who received conventional chemotherapy. Twenty children (median age, 23 months) with medulloblastoma in whom progressive disease developed while they were treated with conventional chemotherapy were then treated with high-dose busulfan and thiotepa followed by ASCR. Of these patients 75% demonstrated a radiographic response to chemotherapy.

For patients with initial local relapses only, an EFS rate of 50% and a median survival rate of 39.5 months were achieved.[1539] A follow-up report of this study demonstrated a 69% 5-year OS in patients with local relapse while eliminating the need for craniospinal radiotherapy in 30% to 50% of patients. The need for a complete resection limits use of this strategy for many patients, especially those with metastatic disease.[1534]

Another chemotherapy-based approach has been the “Head Start” protocols, in which conventional induction chemotherapy followed by high-dose chemotherapy with autologous stem cell transplantation is used in the newly diagnosed setting to delay or defer radiation therapy in infants and young children. “Head Start I” consisted of five induction cycles of cisplatin, vincristine, etoposide, and cyclophosphamide. After this treatment patients with no radiologic evidence of disease, or after second-look surgery or reresection of tumor, underwent myeloablative therapy with carboplatin, thiotepa, and etoposide with ABMR. Radiotherapy was deferred in patients who achieved complete remission. Of 62 children enrolled (median age, 30 months), 37 patients proceeded to ABMR, of whom 15 patients were free of disease and required no further treatment; this outcome resulted in a 3-year EFS and OS of 40% and 25%, respectively. Seven deaths occurred as a result of treatment-related complications. These results are similar to those noted earlier and again demonstrate that a subset of patients can be effectively treated with chemotherapy and avoid radiotherapy.[1540] Head Start II further intensified the induction regimen with the addition of high-dose methotrexate for the patients with the highest risk, specifically patients with high-risk tumors (nonmedulloblastoma) or those presenting with evidence of metastatic spread. A total of 21 patients with disseminated medulloblastoma were treated, 17 of whom had a CR yielding a 3-year EFS and OS of 49% and 60%, respectively.[1153] In this cohort of patients, 13 had a GTR and 10 patients received radiotherapy as part of their upfront or salvage therapy; six patients avoided radiotherapy altogether. For patients with CNS PNETs, this approach appears to confer an improved 5-year EFS and OS of 39% and 49%, respectively.[1249] Patients with nonpineal CNS PNET fared better than those with pineal-based tumors, although metastatic disease at diagnosis, age, and extent of resection were not significant prognostic factors; 60% of survivors were able to avoid radiotherapy. In contrast, this approach has not demonstrated equivalent results for patients with ependymoma with an estimated 5-year EFS and OS of 12% and 38%, respectively, with younger age as the only significant prognostic factor.[969] In this cohort of 29 children with ependymoma, 22 were younger than 36 months and only 8% of patients were radiation-free at 5 years.

To further increase chemotherapy dose intensity, other investigators have followed induction chemotherapy with tandem cycles of high-dose chemotherapy with stem cell rescue. In a small series of 15 infants between 4 and 38 months old with varied histologies, including five medulloblastomas, four CNS PNETs, five malignant gliomas, and one ependymoma, patients were treated with induction chemotherapy. This treatment consisted of three cycles of cisplatin, cyclophosphamide, and etoposide followed by three cycles of tandem high-dose therapy with carboplatin and etoposide and ASCR.[1541] Although the follow-up period was short, the 2-year PFS and OS rates of 52% and 72%, respectively, is encouraging. Furthermore, of the 10 patients who were alive, only five received local radiotherapy, and only one patient with M1 stage medulloblastoma received craniospinal radiotherapy.[1541] Similar results have also been reported by the French Society for Pediatric Oncology in a small series of seven patients with medulloblastoma and CNS PNET using high-dose therapy with busulfan and melphalan.[1542] Although three patients received additional treatment with thiotepa and two patients received additional treatment with topotecan, all patients were able to avoid radiotherapy. The PFS was 71% ± 17%, although longer follow-up will be needed.

With regard to the long-term benefits of adjuvant chemotherapy strategy of delaying or deferring radiotherapy, authors of one infant study evaluated their neuropsychological outcomes in a follow-up report. Of the six children who did not receive radiotherapy, all had intelligence quotient (IQ) scores within the normal range, with a mean of 101, although the five children who had received radiation therapy had lower IQs, with a mean of 85 at 5.8 years and a continued decline to a mean of 63 by 10 years.[1543]

In addition to the use of intensive chemotherapy to defer or omit radiation therapy, radiation techniques themselves have also been optimized in attempts to minimize long-term morbidity. This optimization includes the administration of involved field radiation for infants with brain tumors[291,1130,1535] and the use of proton beam radiation therapy.[261,1544] The Pediatric Brain Tumor Consortium also completed a pilot study to assess the feasibility of adding intrathecal mafosfamide to multisystemic chemotherapy followed by conformal radiation therapy.[291] This study included 93 newly diagnosed infants with embryonal CNS tumors and resulted in a 5-year OS rate of 51% ± 11%.

Specific Management Issues in Infants and Young Children

A more detailed description of the diagnosis and management of individual disease categories was provided earlier, but management issues specific to infant tumors are described here.

Infant Medulloblastoma. Despite significant improvements in the treatment of standard-risk medulloblastoma in older children, the outcome of infants and young children with medulloblastoma remains poor, mainly because of limitations in the use of radiotherapy to the developing brain, increased risk of metastatic disease at presentation, and difficulty in achieving a complete surgical resection in infants.[1545] Although the strategies of delayed radiotherapy with chemotherapy and intensification of treatment with stem cell rescue have shown some promising results in infants and young children, the small number of patients, heterogeneous histologies, and varied staging limit their immediate widespread adaptation.[1153,1541,1542] Salvage therapy in infants and young children has also been shown to be feasible in up to 50% of patients but requires the use of radiotherapy. Thus some cognitive impact and compromise will be required in these patients if disease control is to be achieved with this modality.[1546] Attempts at reduction in radiotherapy dose to reduce neurodevelopmental damage can significantly compromise OS.[1547] Alternative therapeutic strategies are therefore needed in the treatment of medulloblastoma of the infant and young child.

With increasing understanding of the biology of medulloblastoma, it has been recognized that the frequency of different histologic subgroups varies with different stages of development. The nodular-desmoplastic subtype of medulloblastoma occurs most frequently in infants and young children and has been found to be most frequently associated with the SHH subtype and is associated with favorable prognosis.[1548] It has also been reported that children younger than 3 years of age who have nodular-desmoplastic medulloblastoma have a high frequency of germline mutations in the negative regulator of SHH pathway signaling, SUFU.[1549] Although SHH-positive desmoplastic medulloblastomas also occur in adults, those that occur in infants have been found to be molecularly distinct to their adult counterparts.[1550] Desmoplasia is not prognostic in the adult tumors, which have an inferior outcome compared with those that occur in infants.

The incorporation of high-dose methotrexate in chemotherapy regimens has been investigated. In the German HIT-SKK study, intrathecal methotrexate and systemic methotrexate were administered to 43 children younger than 3 years who had medulloblastoma, including 26 patients with M+ disease. The 5-year OS for patients with completely resected tumors, residual tumor, and macroscopic metastases was 93% ± 6%, 56% ± 14%, and 38% ± 15%, respectively, an improvement compared with historic control subjects.[1097] Only 38% of survivors received radiotherapy. Of note desmoplastic histology was highly predictive of good outcome, with an OS of 95% ± 4% versus an OS of 41% ± 11% for patients with classic histology; histology was found to be an independent prognostic marker, along with age younger than 2 years. Although outcomes for children with localized disease or favorable histology was excellent without the use of radiation therapy, the poor outcomes of patients with metastatic disease or unfavorable histology led to the inclusion of involved-field radiation therapy to this treatment protocol.[1551] High-dose methotrexate has also been investigated in the "Head Start II" protocol and was shown to be particularly effective for young patients with high-risk medulloblastoma.[1153] The major concern with the use of methotrexate is that this agent has been associated with white matter changes on MRI, especially when methotrexate is administered after radiation therapy.[1552,1553] In spite of this finding the use of methotrexate continues to be investigated, given the overall poor prognoses for this subset of patients. Stratification of risk groups through better histologic diagnosis, together with an improved understanding of the biology of medulloblastoma, may help improve survival in this age group.[1545,1554]

A recent study that included a cohort of 12 patients with medulloblastoma assessed outcomes of infants and very young children treated with surgery, with adjuvant high-dose chemotherapy followed by proton beam radiation.[1544] Longer-term follow-up of this cohort is required to document both survival outcomes and long-term morbidity. In COG study P9934, children were treated with induction chemotherapy after surgery, followed by age- and response-adapted conformal radiation therapy to the posterior fossa and maintenance chemotherapy.[1130] Four-year EFS and OS were 50% ± 6% and 69% ± 5.5%, respectively. Consistent with other infant studies, children whose histologies were desmoplastic medulloblastoma had superior outcomes compared with those without desmoplasia. Of note the children who experienced recurrence after administration of conformal radiation therapy had progression of their disease outside the radiation field.

Infant CNS PNETs and Pineoblastoma. CNS PNET is a neuroepithelial tumor similar to medulloblastoma but with a significantly worse prognosis.[1210,1555] The most recent WHO classification clarifies the nomenclature of this heterogeneous group of tumors. It was traditionally referred to as sPNET and is now called CNS PNET, not otherwise specified, and includes biologically similar tumors that can also be found in the brainstem and spinal cord.[207] Even though medulloblastoma and CNS PNET are classified together as embryonal tumors, cytogenetic[1238,1239] and molecular evidence from microarray analyses[1029] suggests that biologic differences exist between these tumors. Pineoblastomas are also tumors of embryonal origin with a clinically aggressive course.[1187]

CNS PNETs are the fourth most common brain tumors of infants[1526] and account for approximately 10% of all brain tumors occurring in children younger than 3 years.[1556] It is also the most common malignant brain tumor in the first year of life[1525] and, according to SEER data, has a dismal OS of 19% in this age group.[1517] In a national clinical trial, POG 8633, 13 patients with nonpineal CNS PNET who were younger than 3 years were treated. These patients presented with large, well-demarcated tumors with limited edema. In this study CNS PNET was the most common supratentorial tumor in this age group. Presenting symptoms included seizures, nausea, vomiting, lethargy, irritability, headache, focal motor weakness, and increased head circumference; 12 of 13 subjects had symptoms for less than 1 month at the time of presentation.[1557] For unknown reasons, younger children with CNS PNETs and pineoblastomas present with more aggressive disease and a higher frequency of leptomeningeal disease.[1558,1559] Whether this manifestation is inherent to the biology of the disease or related to clinical factors remains controversial. In a retrospective review of 50 patients with CNS PNET, metastatic disease at diagnosis, extent of initial resection, and tumor site did not affect OS, although it was affected by age younger than 2 years and the use of radiotherapy and chemotherapy.[1216] Similar findings were also reported in 46 patients with CNS PNET registered in the CCG-9921 study; treatment regimen, M stage, extent of resection, and age were not found to be significant prognostic factors.[962] In contrast in the "Baby POG" study, 28 patients with CNS PNET, including 11 with pineoblastoma, were treated, all of whom received chemotherapy and delayed radiotherapy.[1522] This study showed a considerable difference in the 3-year survival between the four patients in whom GTR was achieved (100% survival) compared with the nine patients with a subtotal resection (11% survival). Authors of this study also concluded that chemotherapy did not provide benefit.[1522] No benefit from chemotherapy was seen in the French BBSFOP protocol for 25 patients with supratentorial embryonal tumors, which included 17 patients with CNS PNET treated with chemotherapy in order to delay or omit radiotherapy. Of the five patients with CNS PNET who survived, four underwent salvage therapy with high-dose chemotherapy and/or surgery and radiotherapy.[1560] Results from the Head Start studies have also suggested a benefit from intensification of chemotherapy because 60% of this cohort of 43 patients with CNS PNET avoided radiotherapy and achieved an estimated 5-year EFS and OS of 39% and 49%, respectively.[1249] Interestingly metastasis at diagnosis, age, and extent of resection were not significant factors, although numbers were small and the interpretation of individual subgroups is limited.

Pineoblastoma in infants has been associated with a dismal outcome. In the "Baby POG" study 11 patients were treated, ranging from 1 to 35 months (eight patients were younger than 12 months), and all patients had local recurrences, the majority with metastatic disease. All children died 4 to 13 months from the time of diagnosis, despite the use of radiotherapy in six patients.[1194] Similar dismal results have been reported in the CCG 921 protocol in which eight infants with predominantly nonmetastatic, subtotally resected tumors all had progression of their disease within 3 to 14 months (median, 4 months), with a median time to death of 10 months.[1561] Similarly five children younger than 3 years with pineoblastoma, treated according to the German Pediatric Oncology Group HIT-SKK87 and HIT-SKK92 protocols, all had progression of their disease within 6 months and had a median overall survival of 0.9 year.[1558] Although there have been reports of better survival rates in patients with pineal region PNETs, these patients tended to be older and more often received radiotherapy.[1192,1561]

A treatment strategy for infants and young children with CNS PNETs may involve intensification of treatment, as demonstrated by the "Head Start I and II" experience in which 5-year EFS and OS rates of 39% and 49%, respectively, were achieved.[1249] High-dose chemotherapy and ASCR have also been reported to be successful in a series of newly diagnosed children and adults, which included two infants who avoided radiotherapy. The 4-year PFS and OS rates of 69% and 71%, respectively, were observed.[1562] In contrast the German HIT-SKK87 and HIT-SKK92 studies had PFS and OS rates of only 15% and 17%, respectively, for 29 children between the ages of 3 and 37 months who were treated with chemotherapy to delay radiotherapy. A positive impact on survival was seen in patients who were able to achieve complete resection and those who received radiotherapy.[1563] The use of radiotherapy in some of these patients may improve survival, but radiation therapy diminishes the quality of survivorship.[1564] Findings from the CCG 921 study showed that all children with CNS PNET who received radiotherapy and were younger than 9 years experienced significant developmental delays.[1561] The current recommendations for infants with CNS PNETs include maximal safe surgery, multiagent chemotherapy, consideration of high-dose chemotherapy with stem cell rescue, and focal 3D conformal radiation therapy, if permitted by the field size and tumor location.

Infant Ependymoma. Ependymoma is the third most common tumor of infants and young children and the second most common CNS malignancy in children younger than 3 years who are referred for treatment.[1530] Approximately 43% of ependymomas occur in children younger than 2 years.[1233,1517] Unlike adult ependymoma, most ependymomas in infants and young children occur intracranially and, unlike other infant brain tumors, are predominantly infratentorial.[1565] Negative prognostic factors from several studies have demonstrated the importance of the extent of resection (less than GTR or biopsy) and young age (younger than 3 years at diagnosis).[981,1566,1567] Another prognostic factor that has been reported includes anaplastic histology. However the heterogeneity of anaplasia seen in tumors and the differences in the diagnostic criteria for anaplastic histology by pathologists, which have ranged from 7% to 89%, have made a full prognostic assessment of this factor difficult.[943] An MIB1 or Ki-67 index rating of 20 or higher[1568] may also be a negative prognostic marker.[1569] Although the 5-year OS for children with ependymoma has been estimated at 55% to 66%,[976,978] the 5-year survival for infants and young children remains around 25% and is worse if radiotherapy is delayed or a complete resection is not achieved.[963] The role of chemotherapy remains controversial in this population, even though cisplatin is an active agent against ependymoma.[1570] Several studies incorporating chemotherapy have shown lack of efficacy,[1570] including those with dose escalation such as in "Head Start."[969] In the "Head Start III" protocol, which consisted of maximal surgical resection followed by five cycles of induction chemotherapy with a myeloablative consolidation, excellent outcomes were reported only for infants with supratentorial ependymomas. Infants with infratentorial ependymomas had poor outcomes in the absence of radiation therapy.[1571] POG study 9233 ("Baby POG 2") reported improvement in PFS in infants with ependymoma after the administration of dose-intensified chemotherapy, but no difference in OS was observed.[968]

The importance of radiotherapy in the treatment of ependymoma has been clearly established, and stereotactic radiation therapy administration has been demonstrated to be safe and effective.[461] A phase II study of conformal radiotherapy treating 88 young children, many of whom were younger than 18 months (after chemotherapy and maximal surgical resection were completed), yielded a PFS of 75% ± 6% and reduced early neurocognitive deficits, even though younger patients received 5400 cGy of conformal radiotherapy, supporting the use of the modality in these patients.[951] Although long-term neurocognitive follow-up of this younger population is not yet known, this study formed the basis for the COG clinical trial of conformal radiotherapy, including short-duration chemotherapy in the subset of patients who achieved only subtotal resections. A previous CCG clinical trial (study 9942), in which children with incompletely resected ependymoma received upfront chemotherapy before radiation therapy, has also been completed. Experience from the United Kingdom Children's Cancer Study Group–International Society of Pediatric Oncology collaboration for patients with ependymoma has suggested some benefit from the administration of alternating courses of nonmyelosuppressive chemotherapy with myelosuppressive chemotherapy in patients with incomplete resections who do not have metastatic disease.[1572] In this series of 89 children younger than 3 years, in which nine patients had metastatic disease, preirradiation chemotherapy resulted in a 5-year EFS and OS of 42% and 63%, respectively. In addition the 5-year cumulative incidence of freedom from radiotherapy was 42% in the nonmetastatic cohort. Also patients who received the highest dose intensity had a 5-year OS of 76% compared with those with the lowest dose intensity, who had a 5-year OS of 52%.[1572] All patients with metastatic disease in this study experienced a relapse, and the 5-year OS in this group was approximately 25%.[1572] The outcome of patients with metastatic disease at presentation compared with those with localized disease has ranged from no difference in outcome[963,978] to relapse and death in all patients within 2 years of surgery.[1573] Fortunately fewer than 10% of patients with ependymoma present with metastatic disease, although this rate is slightly higher in infants.[963,978] In a retrospective meta-analysis of prognostic factors of 40 patients with metastatic ependymoma, including 29 children younger than 3 years, those in whom GTR was achieved had the best 5-year EFS and OS of 35% ± 13% and 59% ± 13%, respectively, compared with the 5-year EFS and OS of 25% ± 9% and 32% ± 10%, respectively, for those who did not have GTR.[1574] The EFS for patients who received radiotherapy was 57% ± 19%, and it was 40% ± 22% for those who received combined chemoradiotherapy. For patients treated with chemotherapy alone, the EFS was 20% ± 9%. Because no statistical difference was found in the 5-year OS between patients with M1 and M3 disease (51% ± 16% and 40% ± 9%), even patients with bulky disease can be treated if a GTR can be achieved.[1574]

Infant Glioma. Astrocytoma is the most common tumor in children younger than 3 years,[1556] as well as in infants younger than 1 year, and constitutes 30% of the total, of which 75% are low-grade tumors and 25% are reported as high-grade tumors.[1526] Management of these tumors in infants and young children mirrors the approaches used in older children, including observation for patients with completely resected low-grade lesions, chemotherapy for patients with symptomatic, progressive low-grade tumors, and chemotherapy and radiotherapy for patients with high-grade lesions. One major difference between young children and adults with HGGs is the improved prognosis observed in infants. In the "Baby POG series," 18 children younger than 3 years who were diagnosed with HGG (13 of whom were younger than 12 months) had 5-year PFS and OS rates of 43% ± 23% and 50% ± 14%, respectively.[758] Four survivors completed the 24 months of therapy but did not undergo irradiation because of parental refusal and remained without evidence of recurrence. Similar results have been reported in the French BBSFOP trial, in which 21 children younger than 5 years (13 with WHO grade III tumors and 8 with grade IV tumors) received postoperative chemotherapy and had 5-year PFS and OS rates of 35% and 59%, respectively. Of the 12 survivors, 10 did not receive radiotherapy at the time of reporting.[739] Another retrospective review of 16 patients younger than 3 years showed similar results, with 5-year EFS and OS rates of 29% (standard error [SE], 12%) and 66% (SE, 12%), respectively, although six patients received upfront radiation therapy and an additional six patients received radiation therapy at the time of progression.[1575] In the CCG-945 trial for children with newly diagnosed HGGs, children younger than 3 years were treated with the intent to avoid radiation therapy, including 49 children younger than 3 years. In this cohort of 49 children, the 10-year EFS and OS rates were 29% ± 6% and 37.5% ± 7%, respectively.[1576]

Infant CPC. Choroid plexus tumors account for 1% to 3% of childhood brain tumors, and approximately 30% to 40% are CPCs,[1577] with 70% occurring before the age of 2 years.[1578] Because of the association with Li-Fraumeni syndrome, analysis for the presence of *TP53* mutations is recommended.[1356] GTR has been shown to be prognostic[1579] although technically difficult to achieve because of the highly vascular nature of these lesions.[1526] The role of radiotherapy for the treatment of this highly invasive tumor is controversial.[1580,1581] In the "Baby POG" study it was reported that eight patients had choroid plexus tumors, two of whom were alive without use of radiotherapy.[1579] Other investigators have also reported long-term survival without use of radiotherapy in this group.[1582] Because the number of patients with this rare disease is so small, international collaboration is needed to determine the best treatment strategy for this group of patients. Currently maximal safe surgery and adjuvant chemotherapy constitutes a reasonable approach to avoid or delay radiotherapy,[1526] and salvage therapy is possible, not necessarily including craniospinal radiation therapy.[1583]

Other Tumors

Meningiomas

Meningiomas are rare pediatric tumors that are often seen in conjunction with either NF-2 or after radiation therapy[1584]; they account for 1% to 3% (range, 0.4% to 4.1%) of all childhood tumors of the CNS.[1585,1586] Familial meningiomas have been reported, and thus a detailed family history is required.[1587] In one study of children who received radiation therapy to the CNS for childhood leukemia, meningiomas were found in 20% upon routine

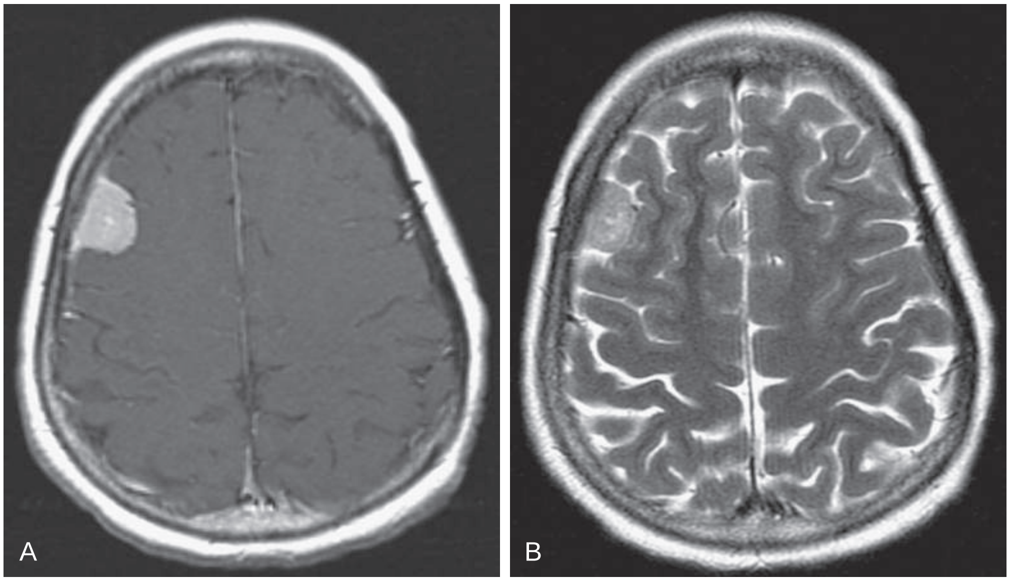

Figure 57-50 Peripheral contrast-enhancing meningioma. **A,** An axial T1-weighted image with use of contrast material. Note the dural tail. **B,** An axial T2-weighted image—bright T2 signal of a right frontal meningioma.

surveillance imaging.[1588] Although meningiomas are uncommon in pediatric patients, they are the second most common primary brain tumor in adults, after gliomas. Meningiomas are frequently identified as an incidental finding at autopsy, suggesting that many of these tumors remain small and asymptomatic. Molecular differences between symptomatic lesions and those that remain asymptomatic suggest that they may be distinct entities.[1589] Meningiomas are known to express hormone receptors, and a number of cell cycle pathways have been implicated in their dysregulated growth.[1590] In a review of the literature, radiation-induced meningiomas were the second most common radiation-induced malignancy after malignant glioma in children treated for a primary malignant neoplasm, with a mean latency of 21.1 and 13.7 years for atypical and benign meningiomas, respectively.[1591] Similarly in a cohort of children with acute lymphoblastic leukemia (ALL) who received cranial radiotherapy (1800 to 2400 cGy) and were monitored by serial scans, meningiomas were the most common tumor, with a mean latency of 21 years.[1588] In one study of patients who were treated with radiation therapy to the CNS for childhood leukemia, 20 years after treatment, it was reported that the incidence of meningioma was as high as 47%.[1592]

Clinical Presentation. The most common clinical presentations in children are seizures (33%), headaches (13%), ataxia (10%), and hemiparesis (10%). Tumor locations are primarily supratentorial (64%), with the remainder distributed infratentorially (16%), intraventricularly (12%), and in the spinal cord (8%).[1585] A few small series have indicated that the location and behavior of meningiomas in children may differ from those in adults, with a greater male preponderance, intraventricular location, increased multiplicity on first presentation, and increased atypical or anaplastic subtypes (15% in childhood).[1586,1593,1594]

Imaging and Histology. Meningiomas are usually well-circumscribed dural lesions on CT and MRI. Areas of calcification are common and are best seen on CT scans. Tumors tend to have low T1-weighted and bright T2-weighted and FLAIR signals. They are usually brightly contrast-enhancing and can be associated with edema.[1595] A “dural tail” is a common finding on MRI scans in which there is dural thickening, tailing away from the lesion (Fig. 57-50). This finding does not indicate a greater propensity of the tumor to invade.[1596] Although most pediatric meningiomas are low-grade lesions (WHO grade I), a higher number of pediatric meningiomas have features of atypia or anaplasia (WHO grades II and III) compared with adult patients, especially in spontaneously arising tumors. This trend can be more pronounced with younger age.[1584] In adult meningiomas good correlation exists between histologic atypia, recurrence, and staining for the Ki-67 monoclonal antibody, a marker of proliferation. Such correlation is not seen in pediatric meningiomas, suggesting that the aggressiveness of pediatric meningioma is not related to proliferation alone.[1597] A number of histologic variants of meningioma can occur in children.[1598-1601] Most meningiomas stain for EMA and vimentin. Loss of chromosome 22 is commonly observed in grade I meningiomas. Loss of heterozygosity of chromosomes 14 and 18 has been associated with tumor grade.[1602] Additional chromosomal abnormalities can be observed in atypical and anaplastic meningioma. In patients without NF-2, a high incidence of mutations in this gene are still detected.[1603] A subset of meningiomas lacking NF-2 mutations have recurrent oncogenic mutations in AKT1 (E17K) and SMO (W535L).[1604]

Management. The management of pediatric meningiomas is difficult to define because of their rare occurrence and association with other mitigating factors, such as prior radiation therapy or association with NF-2.[1584] Treatment guidelines from cooperative groups such as the British Children's Cancer and Leukemia Group are beginning to emerge.[1605]

Meningiomas that are asymptomatic are usually left untreated and followed up carefully for the development of neurologic sequelae, radiologic progression, or radiologic evidence of transformation, at which point neurosurgical intervention should be considered. GTR is usually curative, although the appearance of other lesions is not uncommon. In patients with progressive or symptomatic lesions, radiotherapy can be delivered and can often stop tumor progression. For small unresectable lesions, SRS is also being used with increasing frequency. Meningiomas that develop after radiotherapy in the pediatric population can take on a more malignant phenotype, and early surgical resection should therefore be considered, which may lead to a better outcome, especially if a GTR can be achieved.[1588] The role of chemotherapy in the treatment of meningiomas is limited. Recurrent malignant and atypical meningiomas are difficult to treat successfully, and treatment with chemotherapy has been unsuccessful. Brachytherapy has been proposed for the treatment of patients who have had a relapse, but with high accompanying morbidity.[1606] Partial responses of refractory meningiomas to hydroxyurea[1607,1608] and tamoxifen[1609] have been reported in the literature but need to be confirmed in larger clinical trials.[1610,1611] A phase II trial of combination therapy of imatinib and hydroxyurea in adult patients with relapsed or refractory meningioma demonstrated only modest activity.[1612] A number of new molecularly targeted therapies for meningiomas are now being developed and tested.[1613]

Prognosis. Because of the peripheral nature of many of these lesions, complete resection is achieved in a high percentage of cases. Surgery remains the primary modality of treatment of these tumors and is a major determinant of outcome.[1586] Histologic grade is a further determinant of EFS.[1585] Even though the OS of patients with meningioma has been reported to be close to 90%, length of follow-up is limited or unknown.[1614] In one series extending between 1935 and 1984, long-term survival of 35% in children was reported, with a mean follow-up of 10 years after diagnosis.[1615] The true extent of the morbidity and mortality of this tumor in children is not accurately known[1614] and needs to be the subject of a prospective study by national and international cooperative groups.

Pituitary Adenomas

Although infrequent in pediatric patients compared with adults, pituitary adenomas account for approximately 2.7% of pediatric brain tumors.[1616] The differential diagnosis of pituitary fossa tumors includes craniopharyngioma, GCTs, and Langerhans cell histiocytosis. The vast majority of childhood pituitary adenomas are hormone-secreting or functional, meaning that they produce active hormones, including adrenocorticotropic hormone (ACTH), prolactin, growth hormone, thyroid-stimulating hormone (TSH), luteinizing hormone (LH), or follicle-stimulating hormone (FSH).[1617] Nonfunctioning adenomas account for only 3% to 6%.[1618,1619] Depending on the series, the two most commonly secreted hormones are prolactin and ACTH, followed by growth hormone,[1618,1620-1623] and finally TSH, LH, and FSH.[1617,1624]

Clinical Presentation. The main clinical manifestations of pituitary adenomas are determined by their location and function and usually consist of headaches (with or without signs of raised ICP), visual field defects, endocrine dysfunction, and menstrual irregularities. Other endocrine-specific presentations can be related to hyperprolactinemia, causing secondary amenorrhea and galactorrhea. Cushing disease resulting from ACTH oversecretion presents with hypertension, weight gain, and occasionally diabetes, although gigantism and acromegaly are rarely observed as a result of growth hormone oversecretion. Hypopituitarism can manifest as hypogonadism with delayed or arrested puberty, amenorrhea, and hypoadrenalism, which can manifest as fatigue, hypoglycemia, and/or weight loss. Short stature or growth failure can result from growth hormone deficiency. Hypothyroidism with a low thyroxine and a low-normal TSH level can also be a manifestation, although hyperthyroidism from a thyrotropinoma is a rare finding in childhood.[1624] Nonfunctioning tumors can also have endocrine manifestations, but these manifestations are typically related to pituitary insufficiency.[1625]

Imaging and Histology. The diagnostic workup and management of these tumors includes MRI of the pituitary region with and without contrast, although a CT scan can be useful in extensive disease or in an emergency to rule out local invasion or hemorrhage.[1626] Loss of the pituitary bright spot can indicate compression of the pituitary stalk.[1627] Microcystic and macrocystic structures are also easily identified on MRI (Fig. 57-51).[1627] A detailed biochemical workup in conjunction with an endocrinologist is vital to making a diagnosis and should include determination of serum prolactin, thyroxine and TSH, LH, FSH, serum urea, electrolyte, and morning cortisol levels. Determination of growth hormone, IGF1 and its binding partner IGF-BP3, and urine-free cortisol levels and a low-dose dexamethasone suppression test may be indicated if a growth hormone–secreting tumor or Cushing disease is suspected. Occasionally bilateral inferior petrosal sinus sampling for ACTH may be necessary for the diagnosis of Cushing disease.[1628] Visual field testing should be performed as part of a baseline assessment, and serum β-HCG and AFP should also be part of an initial assessment to rule out a GCT.

Management. Elevated secretion of prolactin can be associated with hyperplasia of TSH and prolactin-secreting cells but without the presence of a pituitary adenoma. Hypothyroidism should be managed before surgical intervention in cases in which hyperplasia may be evident.[1629] In terms of managing patients with

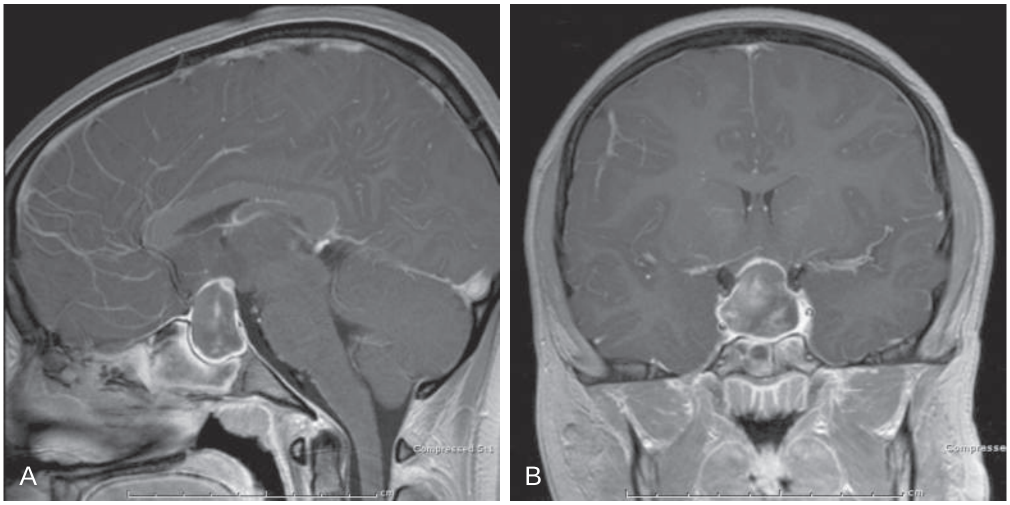

Figure 57-51 Large hemorrhagic pituitary adenoma. **A,** A sagittal T1-weighted image with use of contrast material. **B,** A coronal T1-weighted fat-saturated image.

pituitary adenoma, medical management alone with agents such as bromocriptine or similar analogues may be all that is needed for persons with prolactinoma.[1630] Transsphenoidal surgical resection is typically used for the treatment of growth hormone–secreting and ACTH-secreting tumors,[1631] although a potential role for somatostatin analogs such as octreotide has been proposed for the medical treatment of acromegaly.[1632] Multimodal therapy with medication, surgery, or radiotherapy may be necessary where initial therapy has failed.[1623,1624] Fortunately endocrinologic remission can be achieved in most patients with growth hormone- and ACTH-secreting tumors.[1622]

Multiple endocrine neoplasia type I (MEN1) is an autosomal-dominant disorder characterized by hyperparathyroidism, enteropancreatic tumors, pituitary adenomas, and, rarely, carcinoid, adrenal adenoma, and lipoma. Pituitary adenomas are observed at first presentation in 10% of cases.[1633] Familial isolated pituitary adenoma, characterized by familial pituitary adenomas in the absence of other tumors, is associated with germline mutations in the aryl hydrocarbon receptor-interacting protein gene *(AIP)*.[1634] The prevalence of germline mutations in *MEN1* or *AIP* in seemingly sporadic cases of pituitary adenoma in the pediatric population is high. One study demonstrated that 22% of patients younger than 18 years with sporadic pituitary adenoma had either *MEN1* or *AIP* germline mutations.[1635] In another study *AIP* mutations were reported in 20% of patients younger than 30 years who had pituitary adenomas.[1636] Although formal guidelines are lacking, because there is an increased incidence of genetic disorders such as MEN1 in pituitary tumors in children compared with adults,[1637] the families of index cases of childhood pituitary adenoma should be referred for screening and long-term follow-up.

Prognosis. The long-term prognosis of children with pituitary adenomas is excellent. Remission from abnormal hormone secretion is common; in one review it was achieved in 100% of patients with Cushing disease and 89% of patients with growth hormone secretion.[1622] Although disease control can be achieved in most patients with surgery, 40% may require radiation therapy.[1638] Given the central location of these tumors, this patient population must be carefully followed up for neurocognitive impact, radiation-induced tumors, and additional endocrinopathies because of pituitary dysfunction and radiation-mediated vascular damage.

Hamartomas

Hamartomas are an excessive but focal growth of cells and tissues native to the organs within which they occur. They have been described in the brain, eye, liver, lung, kidney, pancreas, heart, and gastrointestinal tract and in the lymphatic and vascular systems. Although they are benign lesions, hamartomas are regarded by pathologists as a link between developmental malformations and neoplasia. Because of the difficulty in distinguishing these two entities, hamartomas can sometimes be tenuously and variously interpreted as benign neoplasms.[1639] However despite their benign histology, their location and dysregulated growth in the brain can be the source of great morbidity, causing intractable seizures, obstructive hydrocephalus, and developmental delay.

Among the best-known conditions associated with hamartomas in the CNS are NF-1 and TS.[1640] NF-1–associated Lisch nodules are pigmented hamartomas in the iris and are found in more than 95% of affected adults and children older than 6 years; they are thought to be virtually pathognomonic for the condition.[1641] Although Lisch nodules remain asymptomatic and do not usually interfere with vision, they are important as a diagnostic criterion for NF-1. These lesions may be associated with unidentified bright spots seen in patients with NF-1[1642] and have been hypothesized ultimately to be related to neurofibromin levels.[1643] NF-2 results from loss of the tumor suppressor merlin and is characterized by predisposition to the development of multiple tumors, including schwannoma (particularly of the vestibular nerve), meningioma, and spinal cord glioma. Although not a commonly described association, combined pigment epithelial and retinal hamartoma have also been reported in patients with NF-2, although as a rare finding.[1644-1646] Their clinical significance is not clear. TS, like NF-1 and NF-2, results from the loss of the *TSC1* and *TSC2* tumor suppressor genes, which encode for hamartin and tuberin, respectively. These act by downregulating the Akt-mTOR pathway,[1647] as well as by regulating transcription through cross-talk with the Wnt signaling pathway through the ability of TSC1 and TSC2 to form a β-catenin degradation complex.[1648] A pathologic feature of TS within the CNS is the formation of cortical tubers, which are hamartomatous growths, in addition to subependymal nodules and the propensity to develop SEGAs. The clinical manifestation of this disorder is often seizures, cognitive disability, and other systemic manifestations, including dermatologic and visceral changes.[1640]

Several other rare inherited syndromes are associated with hamartomatous lesions in the brain, including Cowden disease, Bannayan-Zonana syndrome, Bannayan-Riley-Ruvalcaba syndrome, and LDD. In considering other conditions that are associated with hamartomatous lesions in the brain, Cowden disease (Online Mendelian Inheritance in Man [OMIM] 158350) is important because it is characterized by the familial predisposition to multiple benign hamartomas. These patients are also at increased risk of malignant lesions in all three germ layers involving most major organs, including the brain, mucocutaneous tissue, breast, thyroid, and uterus,[1649] with multiple tricholemmomas or benign neoplasms of the hair follicle, which are considered pathognomonic.[1650] The gene responsible for Cowden disease on chromosome 10 was cloned by linkage analysis and found to be a phospholipid phosphatase *PTEN* (*p*hosphatase *ten*ascin).[1651,1652] It is mutated in the germline in 80% of patients with Cowden disease, as well as in the Bannayan-Zonana syndrome.[1653] The same gene is also mutated in 60% of patients with Bannayan-Riley-Ruvalcaba syndrome (OMIM 153480), which is manifested by macrocephaly, developmental delay, and intestinal hamartomas. Several authors have reported mutations in the *PTEN* gene in patients with Proteus or Proteus-like syndrome; hamartomatous growths develop in both syndromes. Although rare LDD is associated with hamartomas of the brain resulting in ataxia, increased ICP, and seizures. The underlying lesion is a dysplastic gangliocytoma of the cerebellum, which is thought to be a hamartomatous overgrowth of Cowden disease.[1654,1655] In fact adult-onset of LDD is considered pathognomonic for Cowden disease by the National Comprehensive Cancer Network Guidelines.[1640,1649] Some authors have suggested that these familial hamartomatous syndromes be clustered with Cowden disease and the Bannayan-Riley-Ruvalcaba syndrome into a new category called PTEN hamartoma tumor syndrome, although this suggestion remains controversial.[1656] Recently a consortium was established, which published revised diagnostic criteria for PTEN hamartoma tumor syndrome to address this issue.[1657]

Imaging and Histology. Considerable variability exists in the imaging characteristics and pathologic appearance of hamartomas in the brain. Certain commonly observed features include areas of calcification on CT scan. On MRI scan, most lesions tend to be hypointense to isointense on T1-weighted sequences and bright on T2-weighted sequences and FLAIR (Fig. 57-52).[1658] Hamartomas of the brain are normally noncontrast-enhancing, which can help differentiate them from low-grade astrocytomas. The load of signal abnormality can be correlated with the severity of the symptoms and prognosis in many patients, such as those with TS.[1659] Using magnetoencephalography and concurrent SPECT imaging, precise tuber localization can be achieved and can assist in surgical planning.[1660,1661] Histologic features of hamartomas are highly dependent on their location.

Management. The detailed management of tumors arising from the hamartoma conditions of LDD and Cowden disease, tuberous sclerosis, and neurofibromatosis is beyond the scope of this text. Multidisciplinary team management involving input from the geneticist, neurologist, neurooncologist, neurosurgeon, and affiliated specialists such as the neuropsychologist is highly recommended to provide comprehensive care. Molecular testing of patients and tumor tissues is also mandatory as targeted therapies with new agents emerge. Rapamycin and its analogs and derivatives specifically target mTOR, which is downstream from the PTEN/PI3K/Akt pathway and is common to neurofibromatosis and TS.[1647] Everolimus has been shown in a randomized phase III trial to be effective for the treatment of subependymal giant cell astrocytomas in patients with TS.[1662] Similar therapeutic agents are also available for targeting Ras through the inhibition of farnesyltransferase and are the subject of ongoing clinical trials for progressive plexiform neurofibromas.[1663] Pallister-Hall syndrome, which results in hypothalamic hamartomas, involves abnormalities in the SHH–Gli 3 pathway,[1664] and a number of new molecular inhibitors of this pathway are beginning to undergo clinical investigation.[1665]

Optimal management of hamartomatous lesions of the CNS is typically directed at the presenting symptoms.[1666] Seizures are a common presenting symptom, and treatment with antiepileptic agents is the first approach. Hamartomatous lesions are often refractory to these medications, even when multiple drugs are coadministered. Complete resection of hamartomas is not always required to improve seizure control, because disconnection of the epileptiform focus without gross surgical resection has resulted in significant clinical improvement in hypothalamic hamartomas.[1667]

Prognosis. Although isolated hamartomatous lesions that can be resected have a good prognosis, patients usually present with a number of comorbid symptoms related to the hamartomas and to the underlying associated genetic syndrome. Mental retardation, autism, and behavioral issues can persist. Seizures are not always amenable to surgical intervention, especially in deep structures of the diencephalon. Even in patients who are treated successfully, their underlying genetic susceptibility places them at risk for the development of new lesions.

Astroblastoma

Astroblastoma is a rare glial tumor of the CNS that accounts for 0.45% to 2.8% of all primary brain gliomas[1668] and approximately 0.92% of all pediatric brain tumors.[1669] The tumor was first described by Bailey and Cushing in their 1924 classification of brain tumors,[1030] but some persons argue that the term *astroblastoma* is confusing because the tumor is neither overtly astrocytic nor blastic in nature.[1670] The current widely accepted pathologic description of astroblastoma is that of a generally solid, well-circumscribed mass that is histologically defined by the presence of astroblastic pseudorosettes and perivascular hyalinization.[1671] Ependymoma is an important differential diagnosis because of the clinical and histopathologic similarity between these tumors, which includes perivascular orientation, pseudorosette formation, and immunohistochemical staining with GFAP and EMA. These histopathologic similarities have led to the suggestion that the tanycyte, or ependymal cell, may be a common precursor of ependymoma and astroblastoma.[1672] Even though astroblastoma does have some distinctive features, including broader tapering perivascular processes, lack of fibrillarity, and perivascular hyalinization, which is not seen in ependymoma, this rare tumor continues to be classified under "other neuroepithelial" tumors in the latest WHO classification of CNS tumors.[1673]

Clinical Presentation. The clinical presentation of astroblastoma is usually in children and young adults in the first three decades of life,[1670] with several reports in children 5 years or younger,[1669,1674-1677] as well as a congenital form.[1668] Several case series have shown a female preponderance.[1670,1678,1679] Presenting signs and symptoms are usually of headache and raised ICP because of mass effect or obstruction of CSF flow. The site of the tumor is most often supratentorial, peripherally located in the brain.

Imaging and Histology. Radiologically, astroblastomas appear as large, well-circumscribed, heterogeneous, lobulated, solid and cystic masses, with little vasogenic edema disproportional to their size. This lack of edema is a feature that can also help distinguish astroblastoma from ependymoma and HGGs. The solid component of the mass is described as bubbly, and the MRI T2-weighted signal is isointense with gray matter. Enhancement of the solid component is seen in 75% of cases, and punctate calcification is occasionally seen.[1678,1679]

The histopathologic features of astroblastoma include strong immunoreactivity for S-100, GFAP, and vimentin, with focal staining with EMA.[1673] Histologic grade is considered as either well differentiated, which correlates with the ability to achieve a GTR,[1670] or malignant, with features of anaplasia, which is a poor prognostic marker.[1677] MIB1 immunoreactivity has been observed over a wide range (1% to 18%), although it is unclear whether an increasing MIB1 index rating is related to a poorer outcome.[1670] A formal WHO grade has not yet been assigned.[1673]

Management. Treatment of these tumors includes maximal surgical resection followed by focal or WBRT, especially when features of anaplasia are present. The role of TMZ,[1680,1681] intensive chemotherapy in younger children,[1677] or other forms of chemotherapeutic agents[1669] has not been determined. The establishment of an international registry to gain more information on treatment responses and a detailed understanding of the biology of these tumors has been proposed to optimize treatment approaches for this rare tumor.[1682] To this end studies of chromosomal abnormalities, such as gains of chromosome 20q and chromosome 19[1670] or loss of heterozygosity of chromosome 9p,[1683] are important and help distinguish this tumor from ependymomas. The description of variants of astroblastoma that have rhabdoid features and a better prognosis[1680,1684] warrants further study of this rare tumor.

Prognosis. The prognosis of astroblastoma is in part dependent on the histologic features. Anaplastic lesions do less well than those with low-grade features.[1671,1677] Complete resection is important for long-term survival and may be sufficient therapy for most patients, including some lesions with more of an anaplastic appearance.[1670]

Primary CNS Lymphoma

CNS lymphoma is a rare group of tumors that can arise in the CNS. Although primarily associated with immunosuppression from human immunodeficiency virus (HIV) or other immunodeficiency states, CNS lymphoma has also been detected in patients lacking a prior infectious or immunocompromised history. These tumors are often very responsive to therapy, including radiation therapy and/or chemotherapy.[1685]

PCNS lymphoma in childhood and young adults is an extremely rare tumor, accounting for about 1.2% to 1.5% of all brain tumors,[1686,1687] with an annual incidence rate of 0.02 per 100,000 based on data collected by the Childhood Brain Tumor Trust between 2000 and 2004. These data suggest that approximately 16 new cases per year are expected in the United States.[1032] Children with congenital immunodeficiency syndromes face an inherent 4% overall risk of developing cancer, which is 10,000 times higher than the expected rate. The highest risk groups are ataxia-telangiectasia and common variable immunodeficiency.[1688] Data collected by the Immunodeficiency Cancer Registry have shown a median age of presentation in this group of children to be 10 years, and more than 50% of the cases consist of non-Hodgkin lymphoma, 30% of which were extranodal.[1689] Patients with Wiskott-Aldrich syndrome have the highest proportion of CNS lymphoma among the congenital immunodeficiencies, which is estimated at approximately 3%,[1690] followed by immunoglobulin (Ig)A deficiency, hyper-IgM syndrome, and severe combined immunodeficiency.[1691] Immunodeficiency after organ transplantation also carries a risk of between 1% and 5% for PCNS lymphoma, and increasing rates are being observed in renal, cardiac, lung, and liver transplant recipients.[1692] AIDS, particularly HIV-AIDS in adults, was responsible for a peak in CNS lymphoma in the mid 1990s, with 2% to 13% of adult patients with AIDS affected.[1693] In one study of pediatric patients with AIDS, the Centers for Disease Control and Prevention reported 18 of 6209 patients presenting with CNS lymphoma.[1694,1695] The overall risk of CNS lymphoma was estimated at 17% to 42% in pediatric patients with AIDS.[1688,1696,1697] Subsequent reporting by the SEER program has not shown an increase in the rate of PCNS lymphoma in the 0- to 19-year-old age group, unlike in adults, whose rates have fallen dramatically since the peak in the 1990s.[1698] This finding is probably attributable to the introduction of multiantiretroviral therapies (e.g., highly active antiretroviral therapy) and other therapeutic improvements.[1699]

Although patients with immunodeficiencies are at higher risk of developing PCNS lymphoma, most adult and pediatric patients in whom this malignancy develops are immunocompetent.[1685,1692,1700] The pathogenesis of PCNS lymphoma in the immunocompetent host is unknown. One hypothesis is that systemic inflammatory cells have become trapped in the brain and subsequently transform, isolated from the remainder of the immune system by virtue of the immunologic sanctuary status of the brain. This hypothesis does not fully explain the fact that normally only T lymphocytes traffic through the CNS, although most cases of PCNS lymphoma are of B-cell origin.[1701]

Clinical Presentation. Although the clinical presentation of PCNS lymphoma is in keeping with the diffuse infiltrative growth seen in adult patients and is dominated by cognitive dysfunction, psychomotor slowing, behavioral changes, raised ICP, and seizures,[1702,1703] most pediatric patients present with symptoms of increased ICP, hemiparesis, ataxia, and cranial nerve dysfunction.[1685,1686,1700]

Imaging and Histology. Radiologic features of PCNS lymphoma include enhancing unifocal or multifocal lesions, usually in the periventricular area, although cortical lesions are not uncommon. MRI is the best modality to use because these lesions are characteristically hypointense on T1-weighted sequences and T2 hyperintense tumor with evidence of peritumeral edema.[1702] Most tumors are brightly enhancing upon administration of contrast material. PET and SPECT imaging can also help confirm the presence of lymphomas and identify metastases in the CNS and outside of the brain.[1704-1706] Using the Revised European American Lymphoma classification system, the diffuse large B-cell phenotype accounts for most cases, followed by the small, noncleaved Burkitt phenotype.[1707] Anaplastic large T-cell lymphoma is rare.[1700,1703] Pediatric patients with AIDS, on the other hand, have been found to have small noncleaved B-cell tumors, both of the Burkitt and non-Burkitt types, and are more frequently associated with Epstein-Barr virus infection.[1688,1708]

Management. The treatment of PCNS lymphoma has followed the adult practice because pediatric-based studies to define optimal therapy have not been conducted. Although PCNS lymphomas are aggressive tumors and require intensive treatment, they are responsive to radiation therapy and chemotherapy. Historically treatment for adults with CNS lymphoma consisted of radiotherapy alone, but these patients also had high relapse rates, which led to the introduction of combination chemotherapy using high-dose methotrexate (greater than 1 g/m^2), a treatment that has proven to be effective.[1709] The role of WBRT as part of consolidation therapy in adults is controversial given its toxicity, especially in older adults and when given in combination with high-dose methotrexate. Some persons consider it to be an essential part of therapy and believe it should be excluded only in persons of advanced age or with neurocognitive impairment.[1710] In contrast to the data with high-dose methotrexate, evidence suggests that consolidation with WBRT and high-dose cytarabine or high-dose cytarabine alone does not improve survival in patients who achieve complete remission with high-dose methotrexate-based combination treatment.[1711] With effective salvage regimens such as re-treatment with high-dose methotrexate or treatment options with TMZ, rituximab, and other agents,[1709] a compelling argument exists to exclude WBRT as part of first-line treatment.

Although pediatric patients have been successfully treated with WBRT alone,[1685,1686] this treatment is often too toxic, especially in younger children. In a multicenter retrospective review of 12 pediatric patients who had a 5-year EFS of 70% and OS of 75% (median follow-up of 79 months), only two patients received radiotherapy, and one patient was treated with high-dose chemotherapy and ASCR, confirming that radiotherapy can be excluded from the upfront therapy of these patients.[1700] Most patients in this study received multiagent chemotherapy including high-dose methotrexate (8 g/m^2), high-dose cytarabine, and steroids, with patients having been treated according to the French-American-British LMB-96 protocol (group C for persons with CNS disease). All patients in this retrospective study had received intrathecal chemotherapy, with the exception of one immunocompromised patient who was treated with hydroxyurea only. Similar results have been reported in a recent single-institution retrospective analysis of six pediatric patients with PCNS lymphoma.[1712] All patients were treated with systemic, methotrexate-based chemotherapy and intrathecal chemotherapy. The estimated 5-year survival rate was 83.3% in this cohort. Organ transplantation patients can be treated with multimodality therapy, as discussed earlier, in addition to a decrease in their immunosuppressive regimens,[1713] although care must be taken to protect their grafts.

Prognosis. A recent, relatively large ($n = 29$) multicenter retrospective analysis of pediatric patients with PCNS reported a 3-year OS of 82%.[1714] It should be noted that these results are based on a cohort of mixed immunocompetent and immunocompromised patients. Further improvements in treatment outcome will require a large prospective multinational study that separates immunocompetent and immunocompromised patients with PCNS lymphomas to determine optimum therapy for this rare malignancy.

Dermoid, Epidermoid, and Arachnoid Cysts

A vast array of cysts can occur throughout the CNS,[1715-1717] and although they are not classified as tumors, these CNS lesions can cause significant morbidity and often require surgical intervention. If they are completely removed, recurrences are uncommon, although incompletely resected lesions can lead to a reaccumulation of fluid, resulting in recurrence of symptoms and necessitating further resection[1718] or cyst drainage.[1719]

The benign cysts of the CNS are often divided into two main categories. The first are those that arise from tissue within the CNS, including porencephalic cysts, arachnoid cysts, ependymal cysts, and hemangioblastomas. The second group of cysts consists of those that arise from extracranial tissue and includes teratomas, dermoid and epidermoid cysts, craniopharyngioma, and endodermal, colloid, enterogenous, and Rathke cleft cysts.[1715] Cysts may also arise from infectious origins, such as cysticercosis or toxoplasmosis.

Arachnoid Cysts. Arachnoid cysts are CSF-filled cavities lined by arachnoid cells[1720,1721] that arise from the arachnoid layer of the meninges. They account for approximately 1% of all intracranial space-occupying lesions and are more common in boys.[1716] They are usually congenital and occur in early infancy[1722] but can also occur as a result of inflammation in older children. Arachnoid cysts usually occur in the supratentorial compartment, arising in areas that are rich in arachnoid tissue, with 50% occurring in the Sylvian fissure,[1723] although they can occur anywhere in the CNS.[1724] Arachnoid cysts are often incidental findings on CT or MRI scans obtained for unrelated symptoms. Although usually isolated in their occurrence, multiple arachnoid cysts can be part of inherited syndromes such as the acrocallosal syndrome (a mutation in the *GLI3* gene, OMIM 200990) or the Chudley-McCullough syndrome (OMIM 604213), both of which are associated with agenesis of the corpus callosum. A familial pattern associated with cysts in multiple family members has been reported, one of which includes abnormalities on chromosome 16.[1725] Arachnoid cysts need to be distinguished from cysts associated with malignant primary or metastatic brain tumors, which are thought to develop as a result of a disrupted BBB as a result of the malignant process.[1726]

Clinical Presentation. In infants and children, arachnoid cysts tend to present with increasing head circumference or hydrocephalus, seizures, headaches, and psychomotor retardation.[1716] In the suprasellar region, 90% of patients present with obstructive hydrocephalus,[1727] although precocious puberty has also been recognized.[1728] In this location, it may be necessary to distinguish arachnoid and Rathke cleft cysts from craniopharyngioma, especially because the clinical management of craniopharyngioma differs significantly. Although differentiating these lesions can be difficult, arachnoid and Rathke cleft cysts are usually uniformly cystic and lack a solid component. In contrast craniopharyngiomas are solid in 10% of patients and solid and cystic in 43% of patients. Another distinguishing feature is the presence of calcification in approximately 90% of craniopharyngiomas, a finding that is rare in arachnoid cysts.[1729] Although the neurologic presentation of craniopharyngioma and arachnoid cysts can be similar, 95% of craniopharyngiomas have accompanying endocrine dysfunction, which is usually absent in patients with arachnoid cysts.

Imaging and Histology. The radiologic appearance of arachnoid cysts is usually nonenhancing, and they appear hypodense on CT and isointense to CSF on MRI (Fig. 57-53).[1730] Several theories have been proposed to explain the expansion of arachnoid cysts, which vary from the pulsatile movement of CSF into cyst cavities to osmotic gradients between cysts and CSF.[1716] Analysis of cyst fluid confirms that it is CSF, although the protein content tends to be elevated.[1731]

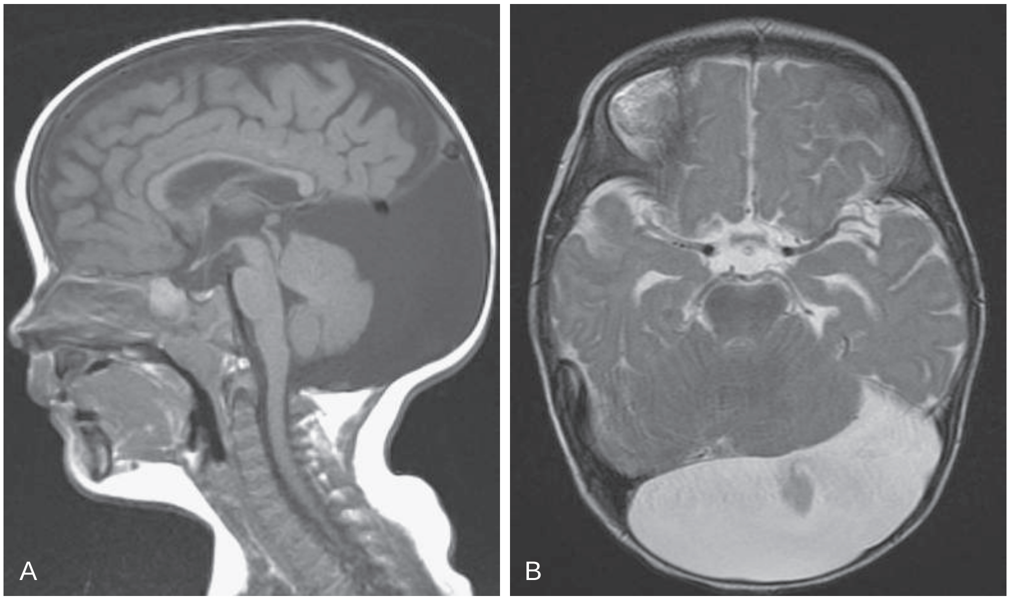

Figure 57-53 Arachnoid cyst. **A,** A sagittal T1-weighted image without use of contrast material. **B,** An axial T2-weighted image.

Management. The management of arachnoid cysts is usually conservative, especially if the patient is asymptomatic.[1732] However approximately 6% of patients with arachnoid cysts will experience complications, including cyst rupture or hemorrhage. Risk factors for cyst rupture or hemorrhage include large cyst size (greater than 5 cm) and head trauma.[1733] A clearly expanding lesion or worsening signs and symptoms will necessitate surgical intervention with cyst fenestration[1728,1734] or cystoventricular shunting.[1719] Newer surgical approaches with endoscopic management have been developed and have been successful.[1727,1735] Retrospective analysis of 1324 cases of pediatric arachnoid cysts demonstrated that open craniotomy for cyst excision or fenestration, endoscopic fenestration, and cystoperitoneal shunting have similar outcomes.[1736] Most patients will have resolution of their presenting symptoms after surgical intervention, although approximately 20% will not experience resolution.[1737,1738] Potential postsurgical complications include infections, subdural hygroma, and CSF leak.[227]

Prognosis. The long-term prognosis of children with arachnoid cysts is excellent. Because fluid reaccumulation can recur, repeat surgical procedures will be required in approximately 20% of patients.[1738] Patients requiring shunting from the ventricles or cysts may require additional procedures as they grow.[227,1739,1740] Seizure control can require lifelong anticonvulsants, especially if complete surgical resection of the lesion is not feasible. Patients with a history of arachnoid cysts may be at increased risk of chronic subdural hematomas.[1741]

Dermoid and Epidermoid Cysts. Dermoid and epidermoid cysts account for 0.5% and 0.8%, respectively, of all intracranial space-occupying lesions[1742] and result from the intrusion of nonnervous tissue, mainly epithelia, into the neuraxis at the time of closure of the neural tube, between the third and fifth weeks of embryonic life.[1718,1743,1744] These cysts are most often located in the major subarachnoid cisterns of the brain—namely, the suprasellar cistern, pineal region, and cerebellopontine angle cistern.[1715] Although benign and slow growing, these lesions can be problematic if they cause local mass effect or obstructive hydrocephalus, and they have a tendency to recur if they are not completely resected or are complicated by secondary infection. In general dermoid cysts are primarily located in the midline in the suprasellar, frontobasal, and cisterna magna areas, although epidermoid cysts can also be found in the suprasellar area. Epidermoid cysts are more common in the lateral skull base around the cerebellopontine angle and are rare in the brain parenchyma or intraventricular region. Both dermoid and epidermoid cysts can occur in the brainstem and spinal cord.[1717,1718,1742,1745]

The presentation of intracranial dermoid cysts occurs in younger patients (10.5 years) compared with epidermoid cysts, which present in adulthood with a mean age of 27 years.[1717] Although usually sporadic in their presentation, intracranial dermoid cysts can have a familial predisposition affecting several generations (OMIM 600679).[1746] Unlike arachnoid cysts, which have a more clearly defined association with intracranial syndromic malformations such as Aicardi syndrome, dermoid and epidermoid cysts do not appear to follow the same pattern. However patients with dermoid cysts can also have associated CNS malformations, such as agenesis of the corpus callosum (OMIM 600679).[1747,1748] In Goldenhar syndrome, which is composed of oculoauricular dysmorphic features and hemifacial microsomia, associated epibulbar dermoid cysts have been reported (OMIM 164210) but do not have a link with cancer predisposition. In contrast Gardner syndrome, a variant of familial adenomatous polyposis with associated predisposition to colorectal carcinomas, includes hyperostosis of the skull and subcutaneous and intraabdominal dermoid cysts (OMIM 175100). Turcot syndrome is characterized by familial polyposis coli with a predisposition to the development of malignant neuroepithelial tumors[1042] and is also associated with mutations in the APC and mismatch repair genes.[1749,1750] The coexistence of Gardner and Turcot syndromes in a family,[1751,1752] coupled with the report of an intracranial epidermoid cyst in a patient with Gardner syndrome,[1753] has suggested that dermoid and epidermoid cysts may share a common pathogenesis. Finally, epidermoid cysts can present as a late effect of a lumbar tap.[1754]

Clinical Presentation. Dermoid and epidermoid cysts can present with a wide array of symptoms, including recurrent fevers, headaches, signs of raised ICP, cerebellar ataxia, behavioral changes, seizures, cranial nerve palsies, increased head circumference, Parinaud syndrome, deafness, long tract signs, visual loss, and cord compression.[1717,1718,1742,1755]

Imaging and Histology. The MRI appearances of dermoid and epidermoid cysts are of well-circumscribed lesions with an accompanying sinus tract that is often visualized on imaging. They produce moderate mass effect but no perilesional edema. They are usually hypointense on T1-weighted imaging and hyperintense on T2-weighted imaging, with enhancement of the solid component (Fig. 57-54).[1718] In a recent study of intraparenchymal epidermoid cysts, the imaging characteristics were similar to extracerebral epidermoid cysts with isointensity to CSF on both T1- and T2-weighted images, with additional diagnostic information from DWI.[1756] Histologically dermoid and epidermoid cysts show overlap consistent with their ectodermal origin. Both are lined by squamous epithelium and some degree of keratin deposition and both lack features of invasion. In addition dermoid cysts can have skin adnexa present in the cyst wall, including hair follicles, sebaceous glands with sebum, and keratin flakes in the cyst fluid.[1717,1757]

Management. The management of dermoid and epidermoid cysts is surgical when intervention is required. Maximal safe resection should be attempted but can be complicated by adherence of the cyst wall to vital structures, limiting the resection.[1718] Subtotal resection is associated with a high rate of recurrence, requiring repeated surgery.[1746] Potential complications include aseptic meningitis in cases of spillage of cyst contents and even malignant transformation.[1743]

Prognosis. Dermoid and epidermoid cysts can recur and continued surveillance is required, especially for lesions that are incompletely resected.

Spinal Cord Tumors

Spinal cord tumors of infants and children are rare and account for 1% to 10% of all tumors of the CNS. They can occur as extradural, intradural but extramedullary, or intramedullary.[1758] There is a slight male predominance, with 58% of cases occurring in males.[1759] Approximately 80% of tumors are low-grade neoplasms. Predominant histologies in the spine from one large series include ependymoma (19%), schwannoma (neurilemmoma; 17%), and astrocytoma[565] (15%).[27] Benign cysts are also common in this location.[1760] Rare histologies identified in this region include neuroblastic tumors,[1761] oligodendroglioma,[1003] gangliogliomas,[602] anaplastic ganglioglioma,[588] nongerminomatous germ cell tumor,[1762] teratoma,[1763] cavernous angioma,[1764] clear cell meningioma,[1765] lipoma,[1766] PNET,[1767] and ATRT.[1768] In a review of 164 patients with spinal cord tumors undergoing resection, the median age was 8.6 years.[1769]

Clinical Presentation. The clinical symptomatology of pediatric spinal cord tumors relates to neurologic impairment concordant with the level of the lesion. Because most spinal tumors grow along the cord, a number of segments are commonly involved. Each segment of the

spinal cord (cervical, thoracic, lumbar, and sacral) can be involved by tumors, and no histologic type is localized to a single area except myxopapillary ependymomas, which are predominantly found in the conus medullaris and filum terminale. Common symptoms of spinal cord tumors include pain (the most common symptom and identified in up to 80% of cases in most series), motor weakness, sensory loss, torticollis, and bladder and bowel incontinence.[1770-1773] Delay in diagnosis is common because of the nonspecific nature of the symptoms early in the disease process.[1774] Patients with evidence of a cerebral mass and spinal cord symptoms must undergo spinal imaging for metastatic disease.

Imaging and Histology. MRI is important in differentiating the location of tumors in the spine (extradural, intradural extramedullary, and intramedullary), as well as differentiating the possible histologies.[1775] As a general rule the imaging characteristics of spinal cord lesions are similar to those of the same histology in the brain. Histologic evaluation of spinal cord tumors follows that of the same lesions in the brain.

Management. Complete or near-complete resection of intraspinal tumors can be achieved in a significant majority of patients. In one large series of 164 patients, a greater than 95% resection was obtained in 76% (125 patients).[1769] Because most spinal tumors are low-grade tumors and can be cured with complete resection, having an experienced neurosurgeon perform the procedure is of utmost importance in achieving a complete resection. Other adjuvant therapies may be considered on the basis of the histology of the tumor. Myxopapillary ependymomas are best managed with complete surgical resection, which is achievable in most patients. Radiation therapy is administered to patients with progressive disease.[947] Patients with spinal ependymoma may have better outcomes than those with similar tumors of the posterior fossa in that many children can be treated effectively with surgery alone, without the need for radiation therapy. In a group of 20 children, a complete resection was achieved in 14 patients, and 6 patients had subtotal resections. None of these six patients received radiation therapy, and yet three remained without progressive disease.[1776] Children with high-grade astrocytomas of the spine who are treated with radiation therapy do as poorly as those with supratentorial tumors.[1777] Low-grade astrocytomas of the spine generally respond to vincristine and carboplatin[1778] or focal radiotherapy.[1779] Chemotherapy (irinotecan and cisplatin) has been used in infants with astrocytomas to delay the need for radiation therapy, with good results in three patients.[1780] Radiotherapy should be reserved for those in whom a complete resection cannot be obtained.[1781] Gangliogliomas are often cured with resection alone; patients with incomplete resection or recurrence can be treated with LGG therapy or focal radiotherapy.[602]

Prognosis. The long-term outcomes for patients with spinal cord tumors are not significantly different from those with brain tumors of the same histology and degree of resection. The morbidities of the tumor and therapies, however, may be significant. Direct neurologic consequences of spinal cord tumors include pain and motor and sensory deficits, as well as urinary and bowel incontinence. Many patients will demonstrate significant improvement in these deficits after treatment. Negative predictive factors for prolonged or permanent motor deficits include older age, unilateral symptoms, preoperative urinary symptoms, and other preoperative deficits.[1782] High-grade astrocytic histology and a short history of symptomatology can also be poor prognostic markers.[1783] Patients who present with sensory deficits do worse than those without this symptom at presentation.[1783] In the case of spinal cord ependymomas, location can effect prognosis, with lesions in the lower half of the spinal cord carrying a poorer prognosis.[1784] Persons with symptoms related to cyst enlargement are most likely to regain function.[945] More than one fourth of patients (27%) experience long-term spinal deformity as a result of their initial laminectomy.[1785,1786] Chronic pain can be particularly difficult in this patient population and requires aggressive management.[1787]

Patients with radiation therapy to the cervical spine can experience paresthesias a few months after therapy that are often described as a feeling of electric shock in the spine. This phenomenon, called Lhermitte sign, is related to transient demyelinization from radiation therapy.[1788] Patients are treated symptomatically, and the sensations typically resolve without the need for intervention.

Chordomas

Chordomas are rare tumors of the skull base that are thought to derive from remnants of the primitive notochord.[1789] Although most cases arise in adults, they can be observed at all ages, including in infants.[1790] Whites appear to be more commonly affected than are African Americans, and males are affected more often than are females.[1791,1792]

Clinical Presentation. Chordomas can present along the axial skeleton, including the skull base, spine, and sacral area. Skull-based lesions typically present with headaches and diplopia. Spinal lesions often result in pain, motor weakness, or sensory deficits. Although initially minor these symptoms tend to progress and eventually result in referral for imaging. Rarely metastatic disease identified on CSF cytology is detected and provides an argument for complete staging of patients, particularly those with atypical or poorly differentiated disease.[1793]

Imaging and Histology. Chordomas are well-circumscribed lesions on CT imaging that can demonstrate areas of calcification. They are hypointense on MR T1-weighted images and bright on T2-weighted images and FLAIR sequences (Fig. 57-55). Chordomas can brightly enhance after administration of gadolinium.[1791] The histologic appearance of chordomas can vary.[1794] Although conventional chordomas (58%) predominated in one pediatric series of 73 cases, 23% were chondroid chordomas and

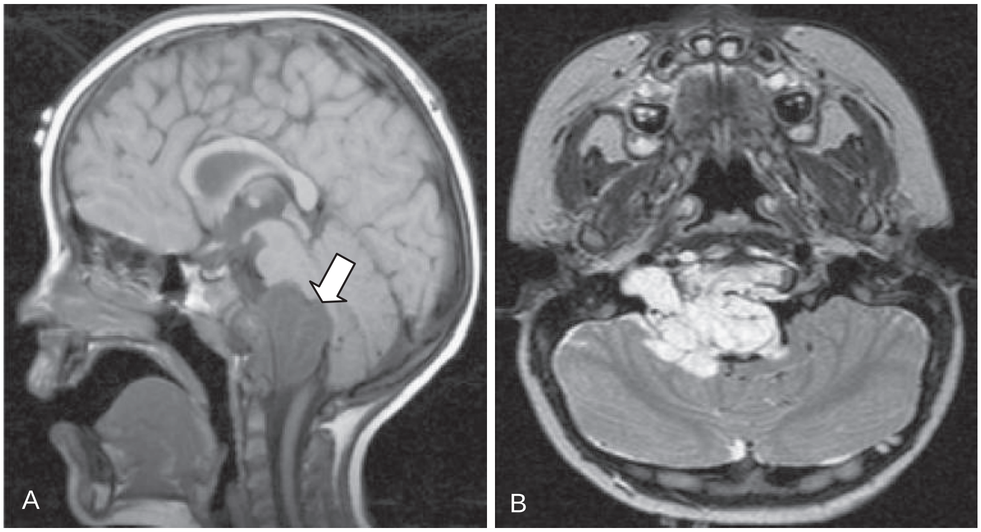

Figure 57-55 A large skull-based chordoma. **A,** A sagittal T1-weighted image without use of contrast material showing a hypointense lesion *(arrow)*. **B,** An axial T2-weighted image.

an additional 19% had high cellularity.[1795] Tumors stained positively for keratin, EMA, S-100, and vimentin. Mitoses and necrotic areas were also commonly observed.[1795]

Management. Radiation therapy can be effective in the treatment of chordomas. In addition to reducing the toxicity of photon radiation therapy to normal structures,[1796] proton beam radiation therapy in combination with IMRT can provide excellent delivery of a high dose to the lesion.[1797] Chordomas are largely resistant to chemotherapy. In patients with more aggressive lesions, or for those refractory to radiation therapy, chemotherapy can be offered. Response to ifosfamide and doxorubicin was reported in one patient with metastatic disease in conjunction with triple intrathecal therapy (cytarabine, hydrocortisone, and methotrexate).[1798] The use of a combination of actinomycin D, cyclophosphamide, and methotrexate or cisplatin and 5-fluorouracil demonstrated no activity in this report.[1798] A retrospective review of six pediatric patients with clival chordomas reported some success with ifosfamide and regimens containing etoposide.[1799] Repeat irradiation with proton therapy and SRS have also been used as salvage therapy in patients who have had a relapse.[1800,1801]

The recent identification of PDGFR-α and PDGFR-β in tumor cells and concurrent expression of the receptors in adjacent stromal cells suggest a possible role for therapeutic intervention with imatinib mesylate.[1802,1803] Another molecular target identified in these tumors includes EGFR; one patient with metastatic disease achieved a partial response with cetuximab and gefitinib.[1804] Modest activity in recurrent chordomas has also been observed with 9-nitrocamptothecin.[1805]

Prognosis. Patients who have chordomas with poorly differentiated features have a worse prognosis than those with classic forms of the disease. Complete resection remains an important prognostic factor. In one large pediatric series, 81% of patients were alive at a median of 7 years after treatment with proton beam radiation therapy.[1795] An elevated MIB1 rating has also been reported as an important predictor of recurrence and OS.[1806]

LATE EFFECTS OF TREATMENT

The long-term and late effects of therapy are a critical concern in pediatric neurooncology.[1807,1808] The developing nervous system is uniquely vulnerable to the long-term effects of radiation therapy, and these effects can become apparent and progressive throughout the life span of the child into adulthood.[1809] Although much of the interest about late effects has refocused on the consequences of radiation therapy, increasing evidence indicates that the presence of the tumor compressing the brain, the surgery needed to remove it, and the chemotherapy provided to treat it all add to the experience of late effects by survivors of pediatric brain tumors.[1810,1811] The improving prognoses of patients with CNS tumors means that more children will be at risk of developing a wide range of late effects of therapy,[1812] including secondary malignancies.[1813] Of particular importance is the focus on the cognitive outcome of children treated for CNS tumors as we shift from the number of survivors to the number of functioning survivors. In association with cognitive deficits, patients can experience depression, anxiety, and social isolation. Survivors have increased risk for suicidal ideation and increased need for psychosocial intervention, and all patients should have follow-up with psychosocial providers to ensure that psychosocial symptoms are not having a significant impact on their lives.[1814,1815] This need for follow-up has required the development of specialized neurocognitive assessment tools[1816-1820] and will also require the development of markers to identify which patients are at risk for late effects from different therapies. Genetic constitution, pharmacogenomics, and individualized pharmacokinetics will need to be assessed when therapy is planned, and appropriate modifications will need to be made to adapt to the unique variables of each individual patient.[1821]

Not all late effects result solely from therapy. Many late effects are the direct result of the tumor or the raised ICP at presentation. For example seizures can occur as a function of the location of the tumor, the therapy, or both. The occasional breakthrough seizure that is relatively well-controlled and not a major concern in childhood can become a significant problem with respect to work and driving while the survivor enters adulthood.[1822] The effect of having had a brain tumor on body image can also be significant. Facial asymmetry caused by tumor infiltration of the brainstem, visual impairment from tumors in the optic pathway, or gait abnormalities from involvement of the motor cortex provide daily reminders to patients that they continue to live with the effects of having had a brain tumor. Raised ICP can also lead to significant vision loss.[1823]

Late Effects of Surgery

Although GTR is the goal of surgery for most types of brain tumors, the consequences of cerebellar or brainstem injury after resection of posterior fossa tumors or the behavioral and endocrine alterations after resection of suprasellar tumors may have a serious impact on the long-term quality of life for a patient. Many surgical morbidities may be acute and can improve over time but other deficits may persist, directly affecting the quality of life for survivors.[1824] The association between surgical dissection of the vermis for tumors involving the fourth ventricle and cerebellar mutism (posterior fossa) syndrome has been well documented, although a precise mechanism has yet to be elucidated. In a report from two large cooperative clinical trials for patients with medulloblastoma, up to 25% of patients were retrospectively identified as having cerebellar mutism syndrome and 92% of cases were deemed moderate or severe. More concerning, 1 year after surgery a significant proportion of these patients were reported to have continued nonmotor speech, language, and neurocognitive deficits, and/or ataxia.[242] Changes in respiratory function related to cerebellar dysfunction can also persist.[1825] Long-term balance problems after posterior fossa surgery remains a major issue for patients and, although this adverse effect may be improved with sparing of the deep cerebellar nuclei when resecting posterior fossa lesions, a significant proportion of children will still have residual deficits.[1826]

The increasing use of third ventriculostomies to treat hydrocephalus has helped reduce the need for prolonged VP shunt management. Patients with VP shunts will need long-term assessment of shunt function and, for patients who were very young at the time of VP shunt placement, repeat surgery to reposition and lengthen tubing may be required. Patients must be aware of the risks of shunt failure (both VP shunts and third ventriculostomies) throughout their lives.

Children with brain tumors who undergo surgical resection as their sole treatment—many with benign histologies—are expected to have few long-term effects from their tumor or treatment. However detailed neuropsychiatric and neurocognitive assessments have revealed that these patients often demonstrate significant abnormalities, including mood, behavioral, and academic difficulties.[429,1827] These results indicate that all brain tumor survivors, including those receiving minimal intervention, require long-term evaluation and support.

Late Effects of Radiation

Radiation therapy can produce acute, subacute, and late effects on the CNS.[1828] The subacute effects of radiation therapy typically become evident 2 to 6 months after treatment and include the radiation somnolence syndrome (RSS), Lhermitte sign, and radiation necrosis.

RSS typically follows within 1 to 2 months of large-volume cerebral irradiation. In a series of 19 adult patients treated with radiation therapy for their CNS tumors, 16 experienced RSS.[1829] Patients typically become lethargic and anorexic and may report fever and headaches. Drowsiness and inability to concentrate are also common.[1829] Many of the symptoms recapitulate those at presentation of the initial tumor and can be very distressing to patients and their parents. The syndrome spontaneously resolves within 1 month in most cases, but occasionally low-dose corticosteroids are required.[1830]

Lhermitte sign is described by patients as an electric shock sensation traveling down the spine on neck flexion, usually arising within several months of cervicothoracic spinal irradiation.[1788] Occurrence after administration of chemotherapy, especially cisplatin, has also been reported.[1831] It is estimated to occur in 3% to 13% of adults[1832] but has not been well studied in the pediatric population. It usually resolves spontaneously within 2 to 3 months, although a few rare cases of prolonged sensory symptoms have been reported.[1832]

Radiation necrosis (Fig. 57-56) frequently occurs within months of treatment, although it can be observed

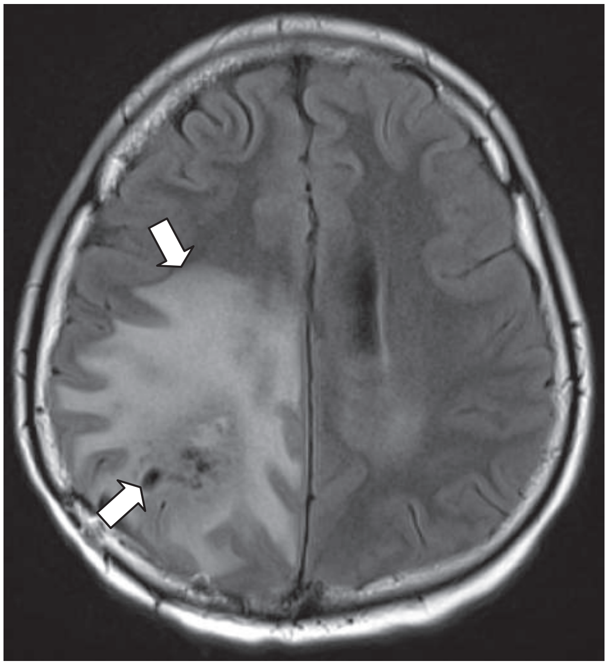

Figure 57-56 Radiation-induced necrosis demonstrating edema *(anterior arrow)* and central necrosis and blood products *(posterior arrow)*.

even years later; a median of 9 months for onset was reported in one retrospective series.[1833] The incidence can increase in association with chemotherapy.[1834] Common findings on MRI include an enlargement of the tumor region, with a central area of necrosis and strong edema signal best demonstrated on T2-weighted or FLAIR sequences. Because of the overlapping symptoms and MRI appearance of radiation necrosis with tumor progression, surgery is sometimes required to confirm the diagnosis and to relieve symptoms. A number of newer imaging modalities are being evaluated to better differentiate tumor necrosis from tumor progression; these modalities include perfusion MRI,[1835] DTI,[1836] and ^{11}C-methionine or ^{13}N-NH3-PET imaging.[1837,1838] On histopathologic examination, if a biopsy is performed, a significant lymphocytic infiltration can be observed.[1839] The occurrence of radiation necrosis is associated with increasing doses of radiation therapy and is most common with doses greater than 6000 cGy and fraction sizes greater than 180 cGy. It is commonly associated with SRS, especially in highly cellular tumors. Small round blue cell tumors of the CNS and glioblastoma multiforme are at particular risk. The treatment of radiation necrosis has historically relied on the use of high-dose steroids to suppress the inflammatory response and resulting edema. More recently the use of antiangiogenic agents has demonstrated activity in this regard. VEGF (initially identified as vascular permeability factor) regulates endothelial cell integrity. Thus agents that target VEGF signaling may become important therapeutic options in this regard.[1840,1841]

The late effects of radiation therapy can occur over a wide time range, and patients have an increase in mortality rate as adults as a result of secondary malignancies, recurrence, and vasculopathy.[1842,1843] On MRI transient T2-weighted signal abnormalities have been identified in patients approximately 1 year after radiation and chemotherapy. These lesions are smaller than 1 cm, and patients are generally asymptomatic. They occur in the high-dose radiation volumes and typically resolve on subsequent MRIs.[1844] These MRI findings can be a cause of concern for tumor recurrence but will usually resolve without therapy.

Late consequences of CNS radiotherapy include subtle or symptomatic, progressive, cognitive deficiencies in areas such as attention[1845] and memory impairment; learning disabilities become apparent[1158] and are related to the dose and volume delivered.[1846] Younger age at the time of radiation therapy is a critical variable. Patients younger than 3 years are at severe risk; those aged 3 to approximately 10 years can anticipate some cognitive decline. Even older children and adults will demonstrate some cognitive deficits after large-volume, high-dose cranial irradiation. It is unclear whether this effect reaches a plateau. Abnormal patterning of the hippocampus in patients undergoing radiation therapy have been observed and may account for some of the memory difficulties in this group of survivors.[1847] Similarly distinct patterns of volume loss in the posterior components of the corpus callosum in patients treated for medulloblastoma have also been reported and follow the radiation dosimetry in these regions.[1848] A detailed evaluation and assessment of the neurocognitive effects caused by therapy requires standardized and validated tools.[1820,1849]

Leukoencephalopathy has been described in children with ALL who received intrathecal and intravenous methotrexate[1850] and whole-brain irradiation.[1851] Similar findings are reported in association with high-dose cytarabine. Leukoencephalopathy may manifest subtle but progressive cognitive decline, as well as seizures. In its severe form, the child becomes demented and incapacitated. MR and CT imaging show diffuse periventricular leukomalacia, with patchy necrosis and calcification. The administration of high-dose intravenous methotrexate after craniospinal irradiation may lead to an especially high risk of leukoencephalopathy and transverse myelitis, and this sequence of treatments should be avoided. Myelopathy may arise as a late consequence of spinal irradiation. Changes in white matter as a result of radiation therapy can have a dramatic impact on cognitive function later in life, and serial assessment of these changes may be used to guide survivorship issues and intervention.[1852,1853] Many patients with significant cognitive decline after radiation therapy, particularly of the temporal lobes, may not demonstrate specific white matter or vascular changes to explain the clinical deterioration.[1854]

Radiation injury to vascular endothelium may lead to ischemic strokes.[1855,1856] If the process is slowly progressive, multiple small collateral vessels may arise consistent with a moyamoya pattern, as seen on MRI or angiogram. Patients with NF-1 are particularly at risk.[1828] This damage to vascular structures of the brain can result in long-term cerebrovascular problems, even decades later,[1857] ranging from acute hemorrhages and cavernous angiomas[1858] to slow and progressive loss of the vasculature and compensatory development of new vessels. The new vessels associated with moyamoya, however, are insufficient to replace the damaged ones.[85] When diagnosed, moyamoya can be corrected with a procedure called pial synangiosis and is well tolerated.[1859,1860]

Secondary malignancies including HGGs, atypical meningiomas,[1861] osteosarcomas,[1862] thyroid carcinoma,[1863] cavernous malformations, and schwannomas have been observed within the treatment field several years after the completion of radiation therapy (Fig. 57-57). Most radiation-induced tumors are not observed before 5 years and can often occur in the marginal areas that received intermediate doses (Fig. 57-58). From a molecular basis, radiation-induced secondary tumors in children do not appear significantly different than those that arise de novo. The prognoses for secondary HGG, atypical meningiomas, and osteosarcomas remains exceedingly poor,[712] thus arguing for the judicious use of radiation therapy, especially for patients with low-grade tumors.[621] Patients with Turcot syndrome, Gorlin syndrome, and NF-1 are more likely to have a secondary malignant glioma after radiation therapy compared with patients who do not have these conditions.[1864]

Pediatric patients with CNS tumors are at high risk for various endocrinologic abnormalities as a result of their tumor[1865] if they needed surgery (especially for pituitary region tumors) or radiation therapy that involves the

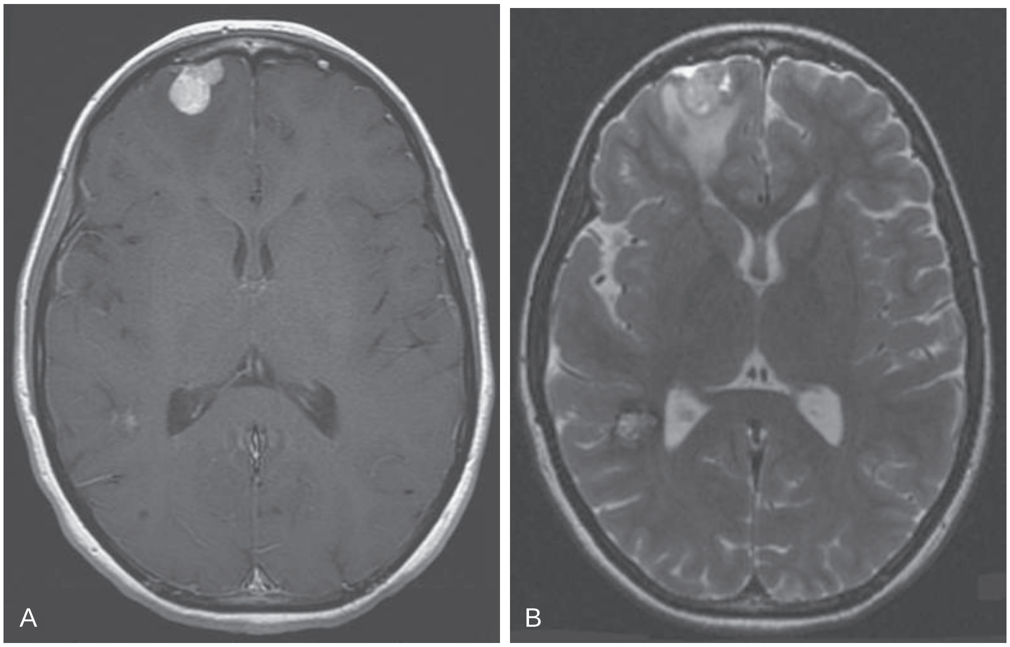

Figure 57-57 Radiation-induced meningioma and cavernous malformation. **A,** An axial T1-weighted image with use of contrast material. **B,** An axial T2-weighted image.

hypothalamus and/or pituitary region.[1866,1867] Growth retardation is usually multifactorial.[1868] Radiation to the pituitary gland may affect the production and release of growth hormone.[1869] Pituitary function may also be impaired by direct invasion of the gland by adjacent tumor. Obesity can be a direct result of radiation therapy on the hypothalamus.[1870] In addition spinal radiation (as part of craniospinal treatment) affects the growth of the vertebral bones and overall bone density, within the radiation field and throughout the body.[1871] Ovarian function can be protected with laparoscopic oophoropexy preirradiation therapy in prepubertal girls in whom the ovaries are likely to be near the midline.[1872] Growth failure after treatment requires active and continued participation by endocrinologists as the cause of growth failure changes from chemotherapy-induced cachexia to radiation-mediated growth hormone deficiency.[1873] Although many patients are discouraged from initiating growth hormone replacement because of concerns for reactivation of the primary tumor or a second malignancy, no evidence exists that these phenomena occur.[1874,1875] In contrast the morbidity related to not replacing growth hormone for persons who are deficient can be severe and lifelong.[1876] Although most centers start growth hormone 1 year after completion of therapy, no evidence suggests that earlier treatment would increase the risk of tumor recurrence. Sleep problems and daytime fatigue[1503,1877] are also highly prevalent, and hypothyroidism and adrenocortical dysfunction can augment these problems and need to be corrected before any additional interventions are initiated.

Proton beam radiation therapy is becoming more common, and children needing radiation therapy for treatment should be evaluated for proton beam radiation therapy if possible because of the decrease in exit dose that would further minimize exposure of normal tissue to radiation.[1878]

Late Effects of Chemotherapy

Although most chemotherapy-related toxicities occur acutely, a number of long-term adverse effects are well recognized. Many of the neurologic effects of chemotherapy become evident at the time of drug administration and will improve after cessation of the drug. In some patients, however, these toxicities can become long-term issues. Peripheral neuropathy is a common late effect of several chemotherapy agents,[1879] particularly vincristine.[1879] Cisplatin and carboplatin mainly affect proprioception and spare pain and temperature sensation. The usual presenting symptoms are painful dysesthesias and tingling sensations in the toes and later in the fingers. Motor fibers are spared. In contrast vincristine produces sensorimotor neuropathies. The first symptoms are usually tingling in the toes and fingers. Loss of ankle reflexes is typically the first objective sign. Continued treatment with the drug leads to loss or decrease in reflexes and motor weakness involving the dorsiflexors of the feet. Patients with preexisting neuropathies may become quadriparetic after treatment with vincristine. Cerebellar syndromes of acute onset may be seen with high-dose cytarabine and occasionally with 5-fluorouracil. These complications are usually reversible within 2 weeks, but severe irreversible damage to Purkinje cells may occur if the drug is given for several months or if the drug is reintroduced at a later time.[1880] Transverse myelopathy is seen with prolonged treatments with intrathecal methotrexate or cytarabine. The risk is higher when combined with spinal irradiation.

Speech, language, and hearing are important components of daily functioning and can often be significantly impaired as a result of the brain tumor itself and its treatment.[1881] Many patients can have significant impairment that requires early and aggressive diagnosis and management.[1882] Radiation therapy can cause long-term hearing impairment,[1883] but platinum agents such as cisplatin and, to a lesser extent, carboplatin can cause significant sensorineural hearing loss in a dose-dependent manner. Although the higher frequencies of hearing, those above the normal hearing range, are usually affected initially, progressive loss can occur over time, including frequencies within the normal range. In one retrospective institutional study, 4% of patients treated with carboplatin and 57% of patients treated with cisplatin experienced significant hearing loss.[1884] The question of whether agents such as amifostine can reduce cisplatin-mediated hearing loss is controversial.[1143,1144] Patients at risk for hearing loss should therefore be followed up regularly by audiologists so that early corrective action (e.g., dose reduction of platinum agents and hearing aids) can be instituted.[1885]

Renal dysfunction is a rare complication of cisplatin toxicity; it can lead to lifelong proteinuria and salt wasting.[1886] Various electrolytes can be lost with renal impairment and may require daily oral supplementation.

Secondary malignancies are a rare but significant late effect of chemotherapy. In children acute myelogenous leukemia is the most common type of secondary malignancy induced by chemotherapy, and it is most frequently caused by intravenous etoposide.[1887] The risk of acute myelogenous leukemia appears to be dependent on the frequency and dose administered and is highest when etoposide is administered weekly, is less when administered monthly, and is very low when given daily in low-dose oral administration. These leukemias tend to occur 3 to 5 years after etoposide administration. Alkylating agents and platinum-based drugs are less commonly implicated. The transient genotoxic damage to chromosomes by chemotherapy may account for this risk.[1888]

A critical measure of the effectiveness of treatment of pediatric brain tumors is the patient's quality of life. Although this broad measure is difficult to define across all heterogeneous tumor types, age at presentation, and presenting morbidities, a greater emphasis on understanding how to optimize each child's potential has become the focus of many treatment protocols. The development of new assessment tools will also be important as new therapies are evaluated based on their efficacy and the quality of life.[1889]

Survivors have indicated the constant stress they feel after the medical team, family, and friends have declared success in curing them and their brain tumors.[1890] They recognize their own impaired social functioning much of the time[1891] and yet can also be unaware of important psychosocial and behavioral issues evident to others.[1892] Depression is a frequent and often poorly recognized outcome in these patients.[1893] Even patients with excellent prognoses, such as those with a history of LGGs, demonstrate chronic medical problems, as evidenced in one report of 87 patients in which 100% of patients had such issues.[1894] Declines in attention and concentration in survivors of pediatric brain tumors are a major problem,[1895] even when compared with other populations that have received therapy directed toward the CNS, such as survivors of childhood ALL.[1896] Part of this effect likely reflects the dosimetry of radiation used for patients with brain tumors, which increases neurocognitive impairment.[1897] Verbal memory difficulties associated with the treatment of tumors in the third ventricular region are significantly greater than those seen in patients with posterior fossa tumors, in whom attention difficulties predominate.[1898] The development of models to assist in the risk assessment of having a poor outcome is needed.[1899] These issues become particularly acute for this population, especially when they reach adulthood, when they are often faced with insurance barriers preventing them from receiving much-needed therapy.[1900]

Given the broad issues faced by brain tumor survivors, it is difficult to develop a single all-encompassing guideline for follow-up care. Multidisciplinary care in dedicated survivor programs can focus resources needed to identify and address issues in this patient population. From the imaging standpoint, many centers have adopted the standard of scanning patients who have completed therapy every 3 months for the first year, every 6 months for the second year, and then yearly thereafter. Routine surveillance of renal and audiologic assessments depends on the field and dose of radiation therapy, as well as the cumulative dose of platinum chemotherapy agents. The frequency of cardiac and pulmonary assessments also depends on particular agents previously used and their cumulative doses. Continued radiologic and blood chemistry surveillance is recommended for most patients as the risk of tumor recurrence decreases and is replaced by increased second tumor risk.

PALLIATIVE CARE

Although clinicians and caregivers focus a great deal of attention on attempts to eradicate disease, a significant proportion of patients with pediatric brain tumors will not survive and, in the process, many often suffer. The early introduction of palliative services, including discussions on the management of all symptoms[1901] and resuscitative measures (e.g., do not resuscitate orders),[1902] can allow patients and families in the terminal phase of care a more peaceful and dignified death.[1903-1905] Early and aggressive management of pain must be anticipated and the necessary expertise put in place.[1906] Children can often participate in discussion of end-of-life care.[1907] Decisions about where the child will die, either at home or in the hospital, as well as other aspects of terminal care must be addressed with the family and caregivers and require institutional support and resources.[1908] Finally, the discussion about the possibility of autopsy is never an easy one. The more time that patients, parents, and families have to consider an autopsy, separated in time from the actual death and grieving, the more likely they are to be able to make a decision that is right for themselves and their families. To understand the patient's disease better so that other children might be spared the same fate is comforting to families who consent to an autopsy.

Although limited by local governing policy, there is a low risk of transmission of cancer via transplanted organs from children with primary CNS tumors because of their infrequent spread outside the brain and spine. Given the severe shortage of organs, consideration of this option should be presented to the patient, family, and transplantation team.[1909]

Many families have expressed the importance of their relationship with the caregiving team. Many families actually feel abandoned after the child has died when communication and interaction with the medical team suddenly ends.[3] A number of palliative care programs and the expanding literature in this area are now available to help parents and caregivers through the grieving period.

BENIGN TUMORS OF THE LIVER
FUTURE CHALLENGES IN TREATMENT OF PEDIATRIC LIVER TUMORS

INTRODUCTION AND EPIDEMIOLOGY

Liver tumors in children account for approximately 1.1% of all malignancies in children younger than 20 years of age according to the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) reports. The age-adjusted incidence rate of liver tumors is approximately 11 per million in infants younger than the age of 1 year and approximately 6 per million in children between 1 and 4 years of age.[1] This translates to approximately 100 to 150 new cases of liver cancer annually in children in the United States.

Liver malignancies in children can be divided into three broad classifications: hepatoblastoma, which accounts for two thirds of malignant liver cancers and the predominant malignant tumor type in young children; hepatocellular carcinoma (HCC), the predominant tumor type in adolescents; and other rare hepatic malignancies of childhood. A spectrum of benign tumor histologies broadens the differential diagnosis of the infant or child with a liver mass.

In an early meta-analysis of eleven separate series totaling 1256 primary liver tumors in children reported by Weinberg and Finegold, 43% were hepatoblastoma, 23% HCC, 13% benign vascular tumors, 6% mesenchymal hamartomas, 6% sarcomas, 2% adenomas, 2% focal nodular hyperplasia, and 5% other tumors.[2] Rare tumors of the liver also include rhabdoid tumors and hepatic germ cell tumors. An international working group recently provided guidelines regarding the histologic classification of pediatric liver tumors.[3]

Most liver tumors in childhood are more common in boys than girls. The male-to-female ratio observed for hepatoblastoma in cooperative group trials has ranged from 1.5 to 1 to 2 to 1; a combined analysis of multiple studies suggests that the male-to-female ratio in hepatoblastoma is 1.65,[4-7,8] consistent with SEER data.[1]

Hepatoblastomas have a unique age distribution (Fig. 58-1). Two peak ages occur, one at birth or within the first month of life and a second broad peak between 16 and 20 months of age. Ninety percent of hepatoblastomas occur in children younger than 4 years of age, and 95% of hepatoblastomas occur by age 5. Although rare, hepatoblastoma has been seen in adults, as described in multiple sporadic case reports.[9-31] A systematic review of hepatoblastoma in adults suggests that these tumors are associated with a particularly poor prognosis, although the time frame over which these cases were gathered

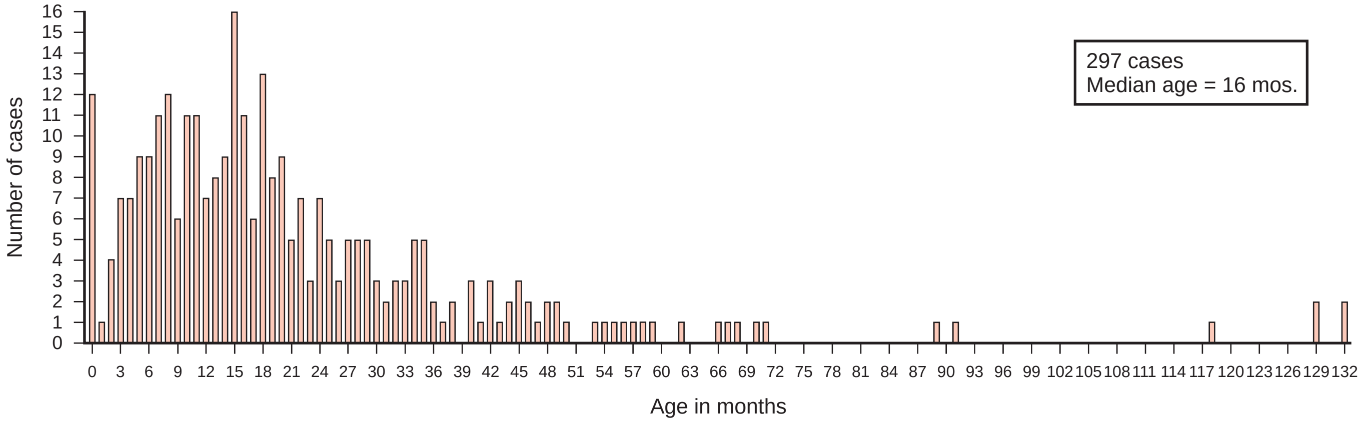

Figure 58-1 Age distribution of hepatoblastoma derived from 256 sequential cases representing all stages and histologies of hepatoblastoma. An initial peak is seen at birth, reflecting tumors developing during gestation. The median age of all children with hepatoblastoma is 18 months, and the oldest age is 78 months. In 99% of cases hepatoblastoma was apparent by 5 years of age.

spanned multiple decades.[32] In contrast hepatoblastomas diagnosed very early in life (i.e., in the neonatal period) are associated with a favorable outcome.[33]

Hepatoblastoma in children older than 5 years of age is often more aggressive than the typical hepatoblastoma, has characteristics of HCC, and has been termed *transitional liver cell tumor*.[34] More recently pathologists prefer to designate this poorly understood entity as *hepatocellular tumor, not otherwise specified*, pending a much-needed and more thorough understanding of the biology of these tumors with features of both hepatoblastoma and HCC.[3] HCCs make up the bulk of liver tumors seen after age 10 years and throughout adolescence and adulthood. As with hepatoblastoma, HCC is more common in male subjects than female subjects.[35-37] The fibrolamellar variant of HCC is a notable exception, with equal occurrence in male and female subjects.[38,39,40]

The incidence of liver tumors has increased over recent decades, perhaps more than any other type of childhood tumor. During a single decade the incidence rates of hepatic tumors in infants younger than 1 year of age increased from 4 to 8 per million.[41] The increase in rates was especially pronounced in female infants, in whom rates of hepatic cancer increased from 2 to 12 per million in a single decade. Ross and Gurney estimated that the average annual percentage change in incidence of hepatoblastoma between 1973 and 1992 was 5.2% for males and 8.2% for females.[42] The rise in incidence of hepatoblastoma has been estimated to be 4% per year between 1992 and 2004[43] and continues to rise in recent years compared with even recent SEER data.[1,44] The largest contributing factor to the increased incidence is thought to be the increased survival rates of premature infants who are at markedly increased risk of hepatoblastoma, as discussed in subsequent sections of this chapter.

ORIGINS OF HEPATOBLASTOMA

Hepatoblastoma has long been thought to have prenatal origins,[45,46] and increasing evidence points to prematurity, prenatal exposures, and overgrowth in early infancy as factors contributing to hepatoblastoma. It has long been presumed that embryonal tumors derive from primitive cells and that hepatoblastoma, as an embryonal tumor of the liver in which cells morphologically resemble cells in the developing embryonal and fetal liver, derives from a primitive hepatic cell. In rodents immature oval cells that proliferate after exposure to hepatocarcinogens express both biliary and hepatocytic markers.[47] These cells are characterized by staining with OV-1 and OV-6 markers. Ruck and colleagues demonstrated the existence of a similar cell type in hepatoblastoma on the basis of marking with OV-1 and OV-6 in a small population of cells within the tumor.[48-50] These OV-1 and OV-6 staining cells account for fewer than 1% of the cells within the tumor and provided evidence to support the existence of a population of stem cells in hepatoblastoma. Fiegel and coworkers analyzed hepatoblastomas for stem cell markers including CD34, Thy1, and c-kit and demonstrated the co-occurrence of these stem cell markers with hepatobiliary markers in ductal cells phenotypically resembling stem cells, which suggests that stemlike cells play a role in the histogenesis of hepatoblastoma.[51] Other markers of hepatic progenitor cells including epithelial cell adhesion molecule (EpCAM), cytokeratin 19 (CK19), octamer-binding transcription factor 3/4 (Oct-3/4), and delta-like 1 homologue (DLK1) have been shown to be expressed in hepatoblastoma tumor cells.[52] NOTCH2, which peaks in the second half of fetal development and then declines toward birth, is expressed in most hepatoblastomas.[53] CITED1, expressed in embryonic mouse liver and a marker of hepatic progenitor cells, is shown to be present in hepatoblastoma, providing another similarity of hepatoblastoma to hepatic precursor stem cells.[54]

GENETIC PREDISPOSITION AND LIVER TUMORIGENESIS

Most cases of childhood liver malignancy are not associated with an apparent major genetic syndrome. However numerous syndromes have been observed in association with hepatoblastoma or HCC, as well as some benign

TABLE 58-1 Genetic Syndromes' Predisposition to Liver Tumors

Disease	Tumor Type	Gene
Familial adenomatous polyposis	Hepatoblastoma, adenoma, hepatocellular carcinoma, biliary adenoma	*APC*
Beckwith-Wiedemann syndrome	Hepatoblastoma, hemangioendothelioma	Multiple candidates
Simpson-Golabi-Behmel syndrome	Hepatoblastoma	*GPC3*
Trisomy 18	Hepatoblastoma	No single gene
Li-Fraumeni syndrome	Hepatoblastoma, undifferentiated sarcoma	*TP53*
Glycogen storage disease types I-IV	Hepatocellular adenoma, carcinoma hepatoblastoma	Glucose-6-phosphatase
Hereditary tyrosinemia	Hepatocellular carcinoma	Fumarylaceto-acetate hydrolase
Alagille syndrome	Hepatocellular carcinoma	*JAGGED-1, NOTCH2*
Other familial cholestatic syndromes	Hepatocellular carcinoma	*FIC1, ABCB11*
Neurofibromatosis	Hepatocellular carcinoma, malignant schwannoma, angiosarcoma	*NF-1*
Ataxia—telangiectasia	Hepatocellular carcinoma	*ATM*
Fanconi anemia	Hepatocellular carcinoma, fibrolamellar cancer, adenoma	*FAA, FAC,* others (20%)
Tuberous sclerosis	Angiomyolipoma	*TSC1, TSC2*

hepatic tumors. A complete summary of genetic syndromes and liver tumors in children is provided in Table 58-1. The major genetic syndromes associated with childhood liver tumors are discussed in the subsequent sections.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is caused by germline mutation of the *APC* gene,[55] FAP is best characterized by the presence of colonic polyps, which without intervention are associated with the virtual certainty that adenocarcinoma of the colon will develop. Germline mutation of the *APC* gene is, however, also associated with a marked increased risk of hepatoblastoma. The risk of hepatoblastoma in children in FAP kindred is estimated to be 800-fold.[56] The risk that a parent with an *APC* mutation will have a child with hepatoblastoma is 0.4%.[57] Because FAP is an autosomal dominant disorder, genetic testing should demonstrate a predisposing mutation in 50% of offspring, such that the risk of hepatoblastoma in an infant who is a documented mutation carrier would be slightly less than 1%. Within a series of consecutive hepatoblastoma patients for whom family histories were obtained, approximately 8% of sequential cases of hepatoblastoma have a family history suggestive of FAP, and abnormalities of the *APC* gene were detectable in all cases.[58]

Also reported in children from FAP kindreds, albeit less commonly, are other liver tumors, including HCCs.[59-62] A benign precursor lesion, hepatocellular adenoma has been reported in a patient with a germline *APC* mutation and colonic polyps.[63] Within resected liver tissue from children with germline *APC* mutations and hepatoblastoma, multiple hepatic nodules were consistent with precursor lesions with potential to progress to either hepatoblastoma or HCC.[64] Presumably the timing of additional mutations or key developmental processes could determine the resulting histologic tumor type in the predisposed liver.

Significantly of nine reported cases of hepatoblastoma in siblings, at least four were in families with FAP;[65-68] Of the remaining reported sibling pairs, one was affected with type 1a glycogen storage disease,[69] and two sibling pairs had no apparent familial syndrome,[70,71] and one recent report of a sibling pair with hepatoblastoma demonstrated an *APC* mutation in only one of the siblings.[72] These reports suggest that whereas *APC* mutation accounts for a significant percentage of familial cases of hepatoblastoma, additional predisposition genetic changes may exist either as a distinct underlying cause of hepatoblastoma or as a modifying factor in infants with an existing *APC* mutation.

The percentage of sporadic hepatoblastoma patients (those without an obvious family history) who carry a germline mutation of the *APC* gene is not well defined. However it has been suggested both that children with hepatoblastoma be screened for germline *APC* mutations and that asymptomatic children in families with known polyposis be screened for hepatoblastoma.[73] Within the *APC* gene genotype-phenotype correlations suggest regions of the gene that predict both the severity of polyposis as well as the presence of extracolonic manifestations. The literature suggests that germline mutations in FAP families with children who are affected by hepatoblastoma can occur throughout the gene (Fig. 58-2) and can also include whole gene deletions or chromosome rearrangements such that the site or type of the individual *APC* mutation cannot be used to predict the occurrence of hepatoblastoma.[58,65,74] This finding implies a risk to all *APC* mutation carriers.

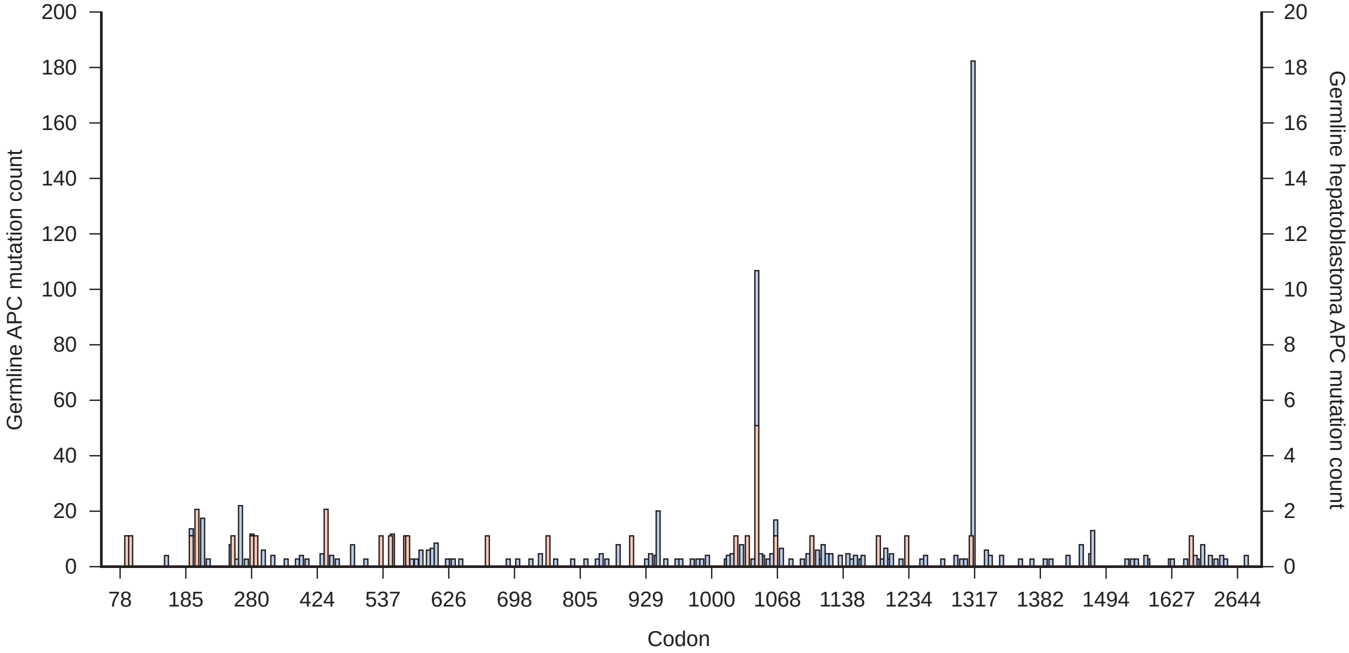

Figure 58-2 Frequency histogram of mutations in the adenomatous polyposis coli *(APC)* gene. Left axis and black lines represent all known APC germline mutations. Right axis and orange lines represent APC germline mutations in children with hepatoblastoma. Germline mutations associated with hepatoblastoma are observed throughout the gene. *(From Hirschman B, Pollock B, Tomlinson G: The spectrum of APC mutations in children with hepatoblastoma from familial adenomatous polyposis kindreds.* J Pediatr *147:263–266, 2005.)*

Overgrowth Syndromes and Hepatoblastoma

Beckwith-Wiedemann syndrome (BWS) is an overgrowth disorder classically characterized by large birth weight, macroglossia, omphalocele, and visceromegaly.[75,76] It is associated with a markedly increased risk of all embryonal tumors, including Wilms tumors, hepatoblastoma, neuroblastoma, and adrenal cortical adenoma.[75,77,78] A registry of children with BWS followed at the National Cancer Institute determined that the relative risk of hepatoblastoma in children with BWS was 2280, higher than the relative risk of any other type of cancer in BWS.[79] Unlike hepatoblastoma and FAP, hepatoblastoma has not been seen in siblings with BWS, despite the extraordinarily high relative individual risk in a patient with BWS. Presumably, this is because of the low incidence of familial occurrence of BWS.

BWS maps to chromosome 11p15, a region known to show loss of alleles in hepatoblastoma[80,81] as well as parental-specific expression of genes (i.e., imprinting), including *IGF2* and *H19*. Molecular subtyping demonstrated that genetic alterations underlying BWS include mutations, epigenetic events involving imprinted genes, or uniparental disomy and that imprinting defects are of two types—those with imprinting defect at the imprinting control element 1 (IC1) at distal 11p15.5 and involving IGF2 and H19 hypermethylation and those with a defect at the imprinting control element (IC2), which is more proximal and involved imprinting changes of KvDMR1 and KCN11OT1.[82,83] One series demonstrated that significantly more neoplasia is noted with either uniparental disomy or imprinting defects at IC1,[82] although hepatoblastoma has been observed in BWS patients with mutations at the IC2 locus.[83] Although differences may exist specific to the type of underlying genetic alteration, it is not possible at this time to tailor screening recommendations to genetic subtype. Present screening recommendations involve periodic ultrasonography of the abdomen and measurement of serum alpha-fetoprotein (AFP).[84-86] In a series of tumors detected in children with BWS who underwent such surveillance, all tumors were small and resectable at diagnosis.[84] Because hepatoblastoma has been noted to occur in the early neonatal period in BWS, some experts recommend screening at an early age.[87] Even though AFP levels are normally very high in the neonatal period, screening with AFP should confirm a downward trend in the absence of tumor.

Simpson-Golabi-Behmel syndrome (SGBS) is an X-linked syndrome characterized by overgrowth with clinical features reminiscent of BWS, including an increased risk of embryonal tumors. Individual cases of SGBS with hepatoblastoma have been reported.[88-90] The underlying gene for SGBS, *GPC3,* is highly expressed in hepatoblastoma compared with normal liver, which is consistent with a potential role in the tumorigenesis of hepatoblastoma.[91-93] Although no longitudinal tumor surveillance studies have been carried out for SGBS, the overlap in tumor types observed suggests that surveillance similar to that used for BWS may be appropriate.

Sotos syndrome, an overgrowth syndrome that has clinical features overlapping with BWS and is associated with a predilection for tumors, has been reported in a child with hepatoblastoma.[94,95] No large series have been reported, however, and the benefit of screening is unclear at this time.

Other Syndromes

Li-Fraumeni syndrome predisposes affected individuals to multiple tumor types in childhood and early adulthood.[96,97] Although liver tumors are not typically included in Li-Fraumeni syndrome, hepatoblastoma has been reported in two Asian Li-Fraumeni kindreds.[98,99] A kindred has also been reported in which a child developed undifferentiated (embryonal) sarcoma of the liver.[100] Acquired mutations of the *TP53* gene in hepatoblastoma tumor specimens, however, are rare or absent but have been reported in the undifferentiated embryonal sarcoma of the liver.[101-103]

Both hepatoblastoma and HCC have occurred in children with primary biliary atresia.[104,105] However it is unclear whether liver tumor development in children with biliary atresia is a complication resulting from liver disease or whether a common predisposition to both biliary atresia and tumor development exist. Significantly the same immature cells thought to share similarities to stem cells seen in hepatoblastoma are also seen in biliary atresia.[106] Multiple cases of hepatoblastoma and trisomy 18 have been reported.[107-113] This is somewhat notable in that trisomy of chromosome 18 is not seen as an acquired event despite the observation of multiple other recurring trisomies.[114]

Hepatoblastoma has been reported in a female subject with monosomy 7 myelodysplasia, a predisposition syndrome not previously seen with hepatoblastoma.[115] Hepatoblastoma has also been reported in neurofibromatosis type 1, although it is not characteristic of this disorder.[116]

A recent report has noted a possible association of hepatoblastoma with prune-belly syndrome, a congenital disorder of lax abdominal musculature and urogenital abnormalities.[117] A review of data from the Children's Oncology Group (COG) demonstrated a significant association with kidney and bladder congenital abnormalities.[118]

Genetic Syndromes and Hepatocellular Carcinoma

HCC, in contrast to hepatoblastoma, is seen in genetic syndromes that are characterized by hepatic cirrhosis. Progressive familial intrahepatic cholestasis, a condition marked by neonatal hepatic cirrhosis, is associated with liver tumor development in children. Both HCC and cholangiocarcinoma are known to occur in this disorder. The disorder, also known as Byler disease, is a heterogeneous syndrome.[119] The underlying genetic etiology is a germline mutation of the *ABCB11* gene, which encodes a bile salt export pump.[120] In a series of 11 cases of HCC in children younger than 5 years with neonatal hepatitis with clinical characteristics of familial intrahepatic cholestasis, 10 had immunohistochemical evidence of a deficiency in bile acid transporter bile salt export pump.[121] In all patients in whom genotyping was possible, a germline mutation of the *ABCB11* gene encoding bile salt export pump was detected.

Alagille syndrome is an autosomal-dominant disorder characterized by a characteristic facies, congenital heart disease, intrahepatic cholestasis with neonatal jaundice, and a paucity of hepatic bile ducts resulting in neonatal jaundice. The liver pathology may progress to frank cirrhosis. HCC has been reported in children with Alagille syndrome.[122-127] The vast majority of these Alagille syndrome–associated HCCs occur in boys. In one family three children were reported with HCC in the absence of any other type of liver disease other than the Alagille syndrome.[123] Alagille syndrome is associated with germline mutations in the *JAGGED1* gene, the endogenous ligand for *NOTCH2*, a developmental gene involved in controlling maturation of the heart and liver.[128] In a minority of cases of Alagille syndrome, in which the *JAGGED1* gene is not found to be mutated, the *NOTCH2* gene itself is mutated.[98,129] It has been shown that the mechanism of liver disease in Alagille syndrome may relate to an increased expression in hepatocyte growth factor in cells that carry *JAGGED1* mutations.[130]

The family of glycogen storage disorders has been associated with liver tumorigenesis. Glycogen storage disease type I has been reported in association with benign adenomas, HCC, and hepatoblastoma, although the latter has been reported only in adolescents.[69,131,132] Similarly glycogen storage disorder type III has been associated with HCC,[133] and type IV has been associated with hepatocellular adenoma.[134] Because HCC is known to occur in diseased liver, with long-term follow-up HCC may be considered a complication of increased survival of patients with glycogen storage disease.[132,135]

Hereditary tyrosinemia type 1, characterized by the deficiency of fumarylacetoacetate hydrolase is likewise associated with HCC in the setting of severe liver disease.[136]

Fanconi anemia is associated with liver tumors, although the association has been almost always reported in association with the use of androgenic steroid treatment.[137-143] In a review of 1301 reported cases of Fanconi anemia, 2.8% of subjects were reported to have a liver tumor.[144] The most common type of liver tumor reported in Fanconi anemia is HCC, but adenomas are also seen in these patients. The incidence appears to increase with age and does not appear to plateau. In multiple instances liver malignancy was seen in patients with Fanconi anemia who also had a diagnosis of leukemia. The extent of the associated androgen treatment with development of hepatic malignancy versus the effect of the underlying genetic defects in DNA repair as manifested by chromosome breakage in Fanconi anemia is unclear, but a review of the association of androgens and liver tumors suggests that patients with Fanconi anemia develop liver tumors after smaller and briefer androgen exposure than do individuals without Fanconi anemia.[145] It is also unclear whether there is a difference among the genetic subtypes of Fanconi anemia with regard to the predisposition to hepatic and other malignancy.[146]

Genetic Syndromes and Other Benign Liver Tumors

In addition to syndromes predisposing to malignant liver tumors, several syndromes are associated with benign liver tumors. Tuberous sclerosis has been linked to development of benign hepatic angiomyolipomas.[147,148]

Although these hepatic growths are not as common as renal angiomyolipomas, which may develop in as many as 80% of patients with tuberous sclerosis, the hepatic lesions are evident in imaging studies in approximately 13% of patients with tuberous sclerosis, according to one study.[149]

PREMATURITY AS A RISK FACTOR

One of the most intriguing aspects of hepatoblastoma is its association with premature or low-birth-weight infants. This association was initially reported by Japanese investigators who analyzed patient diagnoses and birth weights in the Japan Children's Cancer Registry over the 9-year period from 1985 to 1993.[150] It was found that 3.9% of patients with hepatoblastoma were of very low birth weight. Moreover it was observed that when data were subdivided over 4-year periods, the percentage of hepatoblastoma cases of low birth weight rose from 0.7% in 1985 to 1989 to 8.6% in 1990 to 1993 and demonstrated a linear increasing trend. The risk of hepatoblastoma has also been shown to be inversely proportional to birth weight.[151] The relative risk for an infant between 2000 and 2999 grams is 1.21, whereas the relative risk for an infant of less than 1000 grams is 15.64.

Data from the Children's Cancer Group survey confirmed the preponderance of former premature infants in a series of 76 patients with hepatoblastoma.[152] A second confirmation in the United States comes from the California population-based cancer registry, which also reported an elevated risk of hepatoblastoma in children of very low birth weight.[153] This study also pointed out that the age of diagnosis of hepatoblastoma in children of low birth weight was actually older than that of children of normal birth weight, which could partly be explained by gestational age.

It has been speculated that the increase in the percentage of low-birth-weight infants among children with hepatoblastoma may be partially caused by the increased survival rates of low-birth-weight infants. It is also believed that the increase in survival rates of premature infants at risk for hepatoblastoma may contribute to the overall increase in childhood liver tumors.

Indeed the rise in the rate of hepatoblastoma has been found to be consistent with the risk in births of low-birth-weight infants.[154] However whether the pathways by which low-birth-weight infants develop hepatoblastoma involve key exposures in the newborn period, increased sensitivity of the liver in premature infants to potential carcinogens, disruption of the normal process of liver development by premature birth, or a combination of these factors has yet to be defined. One small single-institution study, in which treatment records of five infants who developed hepatoblastoma were compared with those of infants of similar birth weights who did not develop hepatoblastoma, suggests that perinatal intensive long-term treatments contribute to the development of hepatoblastoma.[155] A somewhat larger study comparing 12 hepatoblastoma cases and 75 birth weight–matched controls suggests that the duration of oxygen therapy, use of furosemide, and length of time taken to regain body weight at birth were factors in predicting the likelihood that hepatoblastoma would develop in premature infants.[156] A study from the United Kingdom reported that polyhydramnios and either eclampsia or preeclampsia are more common in children with hepatoblastoma compared with those without hepatoblastoma, and that the eclampsia or preeclampsia observed was also associated with low birth weight.[157]

A recent case-control study of 600 COG patients with hepatoblastoma (AEPI04C1) has examined exposures in low-birth-weight and other infants with hepatoblastoma and has not found an association with maternal illness or medication use during pregnancy or infertility treatment and hepatoblastoma.[158,159] Previously use of assisted reproductive technology was postulated to be a contributing factor, although it is thought that it may contribute to hepatoblastoma development only through the associated risk of BWS and assisted reproductive technology (ART), but not as an independent risk factor.[159,160]

ENVIRONMENTAL EXPOSURES AND HEPATOBLASTOMA

An early epidemiologic case-control study of risk factors for hepatoblastoma by Buckley and colleagues, based on parental interviews, revealed an association of hepatoblastoma with maternal occupational exposure to metals, such as those used in welding or soldering (odds ratio [OR] = 8); petroleum products such as lubricating oils or greases (OR = 3.7); and paints or pigments (OR = 3.7). There was also a significant association with paternal occupational exposure to metals (OR = 3, $P = .01$) and a marginally significant association with paternal occupational exposure to petroleum products (OR = 1.9).[161] Although the aforementioned study did not find an association of parental smoking with hepatoblastoma, this has been reported in several subsequent studies.[162-164] The risk of hepatoblastoma in children of parents who smoked was approximately double in all three studies. Indeed in 2009 the International Agency of Research on Cancer declared that parental smoking is a carcinogen in the developing liver. Subsequent findings have been variable, however. A recent report from COG, the largest etiologic study to date, reported no association between smoking and hepatoblastoma. Variability among studies, however, could be based on small numbers and differences in reporting and overall smoking prevalence in the different populations. Although alcohol clearly plays a role in cirrhosis of the liver and HCC in adults, the COG study reported no association with parental alcohol use and hepatoblastoma in offspring.

VIRAL HEPATITIS AND LIVER TUMORS IN CHILDREN

Viral hepatitis infection has historically accounted for a large percentage of HCC cases. Before the introduction of the hepatitis B vaccine in Taiwan, HCC accounted for 80% of cases of liver tumors in children.[165] With the introduction of the hepatitis B vaccination in 1984, rates of liver tumors in Taiwanese children older than 6 years dropped significantly, from 0.70 per 100,000 from 1981 to 1986 to 0.36 per 100,000 between 1990 and 1994.[166] The decrease in rates of HCC after introduction of the vaccine was more pronounced in boys than in girls. In fact the incidence of HCC decreased in boys but not in girls.[167] The male-to-female incidence of HCC in Taiwan steadily decreased from 4.5 per 100,000 in 1981 to 1986 to 1.9 per 100,000 in 1990 to 1996, 6 to 12 years after the introduction of the vaccine. The reasons for these sex-related differences in responses to the vaccine are not known.[168] It has been demonstrated that among children with hepatitis B the presence of a deletion of the pre-S region of the hepatitis B virus was an additional risk factor for the development of HCC (OR = 36.69).[169]

PRESENTATION AND EVALUATION OF THE CHILD WITH A LIVER MASS

Aside from patients with known genetic syndromes (discussed in the preceding sections), most cases of hepatoblastoma occur in otherwise well children who present with an abdominal mass, often with some degree of abdominal discomfort.

Isosexual precocious puberty has been observed in some boys as a presenting finding in hepatoblastoma and occurs secondary to tumor production of chorionic gonadotropin.[170-182] In one study of 48 children, the incidence of precocious puberty in children with liver tumors was 6%.[183] To the authors' knowledge, there are no known cases of precocious puberty associated with hepatoblastoma in girls.

Laboratory evaluation of the child with a liver mass should include a complete blood count and liver function tests, as well as AFP and β-human chorionic gonadotrophin tumor marker levels. The platelet count is often high in hepatoblastoma but is not diagnostic of hepatoblastoma among children with liver tumors.[184] This thrombophilia is associated with high serum levels of thrombopoietin (TPO), also known as c-Mpl ligand. Normally synthesized in the liver, TPO has also been shown to be expressed in hepatoblastoma tumor tissues and is present at higher than normal levels in the serum of patients with hepatoblastoma.[185] In a large series of patients of various ages (13 to 84 years) who had hepatic tumors, thrombocytosis was noted in 2.7%. The high platelet count was correlated with higher serum TPO levels.[186] Other components of the complete blood count are usually normal insofar as bone marrow involvement with liver tumors has not been reported.

AFP is the primary serum marker that is used diagnostically and prognostically, as well as in surveillance. A sample should be obtained in the initial evaluation of any child with a liver mass.[187] AFP levels are markedly elevated in more than 90% of hepatoblastomas and more than 50% of HCCs. Care should be taken in interpreting AFP levels in the young infant because levels are normally very high at birth and decline to less than 10 ng/dL over the first year of life. Of note is that some liver malignancies—notably the small cell undifferentiated subtype of hepatoblastoma as well as the fibrolamellar variant of HCC—are not associated with elevation of the AFP.[188,189] Likewise, sarcomas and rhabdoid tumors are not associated with elevated AFP. The International Society of Oncology Epithelial Liver Group (SIOPEL) has demonstrated that hepatoblastomas with low AFP levels at diagnosis (less than 100 ng/mL) tend to present at a higher stage and are associated with a poor outcome.[188] A low AFP level has also been noted to be a marker of poor outcome across multiple studies compiled and analyzed by the Children's Hepatic Tumor International Consortium (CHIC) group.[190] The β-human chorionic gonadotrophin level is only occasionally elevated in hepatoblastoma, usually in cases that present with precocious puberty. The β-human chorionic gonadotrophin level is also elevated in the rare choriocarcinoma of the liver, as well as teratomas.

Evaluation of a child with a liver tumor should include a thorough family history to document specific cancers in relatives, with notation made of any early-onset colon cancers or colectomies, in addition to the presence of thyroid cancers or medulloblastoma, which can be part of FAP syndrome. Testing for germline mutation of the APC gene may be indicated; if performed, it should include appropriate genetic counseling. These patients with hepatoblastoma and germline APC mutations will require long-term surveillance for colonic polyps and tumor development.

In addition the medical history should note the birth weight, history of prematurity, and presence or absence of stigmata of neonatal overgrowth, including omphalocele and hemihypertrophy, which would suggest BWS and a risk for other embryonal tumors.

STAGING

Although North American trials have traditionally used a postsurgical diagnostic staging group, applied after the initial surgical procedure (biopsy or resection), the European system, based on the appearance by imaging before chemotherapy and surgical resection (PRETEXT), is being adopted worldwide. PRETEXT stages I through IV reflect the number of sectors that are involved with tumor. Other components of the staging system reflect extension into the vena cava , extension into the portal vein, extrahepatic abdominal disease, or distant metastases. The SIOPEL staging is shown schematically in Figure 58-3. A comparison of the prior North American staging and the current SIOPEL staging is shown in Table 58-2.

Figure 58-4 demonstrates a small hepatoblastoma tumor image that was initially diagnosed by surveillance ultrasound in a patient with BWS. This tumor involved two sectors and as such is classified as PRETEXT II, but because it was completely surgically excised after diagnosis, it would be stage 1 using the North American staging system. Figure 58-5 demonstrates a multifocal hepatoblastoma that involves all four sectors and had metastatic lesions in the lung; therefore it is PRETEXT IV by the North American staging system. If the patient had not had metastatic lesions, the tumor would be stage 3 according to the North American system but still PRETEXT IV.

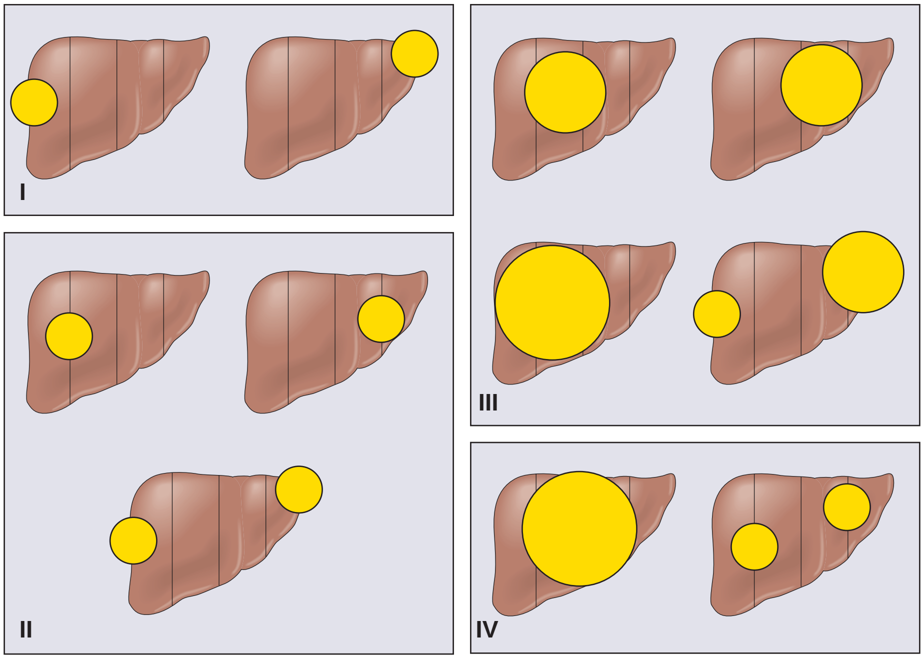

Figure 58-3 Pretreatment imaging-defined staging protocol presurgical staging system used by the International Society of Pediatric Oncology to predict outcome. The liver image is divided into four sectors, and tumor stage is defined as the number of free sectors. In this system, stage is further defined by extension of tumor beyond the liver as *V* indicating extension into the vena cava or all three hepatic veins (or both), *P* indicating extension into the main or both left and right branches of the portal vein, *E* indicating extrahepatic disease proved by biopsy, and *M* indicating the presence of distant metastases.

TABLE 58-2 North American Postsurgical Staging Versus European Presurgical Staging

	North American Staging	European Staging SIOPEL/PRETEXT
	Postsurgical Staging	Presurgical Staging
Stage 1	No metastases; tumor completely resected	Tumor involves only one quadrant; three adjoining liver quadrants free of tumor
Stage 2	No metastases, tumor grossly resected with microscopic residual disease (i.e., positive margins, tumor rupture, or tumor spill at the time of surgery)	Tumor involves two adjoining quadrants; two adjoining quadrants are free of tumor
Stage 3	No distant metastases, tumor unresectable or resected with gross residual tumor, or positive nodes.	Tumor involves three adjoining quadrants or two nonadjoining quadrants; one quadrant or two nonadjoining quadrants are free of tumor
Stage 4	Distant metastases regardless of the extent of liver involvement.	Tumor involves all four quadrants; there is no quadrant free of tumor

PRETEXT, Pretreatment Imaging-Defined Staging Protocol; *SIOPEL,* International Society of Pediatric Oncology Epithelial Liver Group.

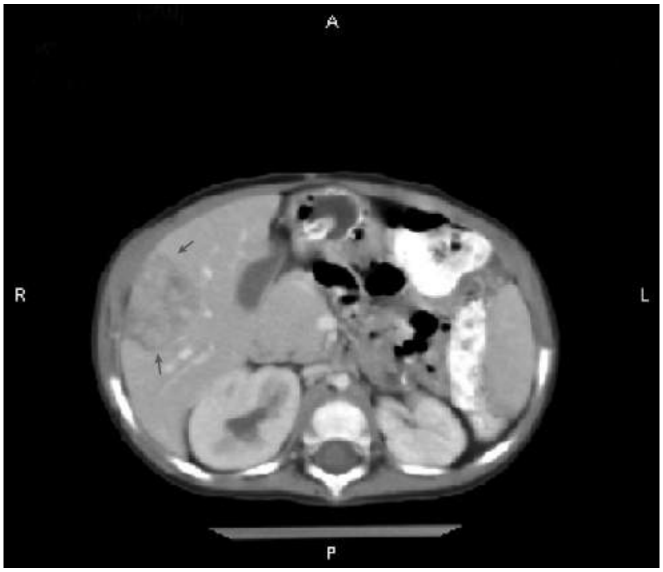

Figure 58-4 Computerized tomography scan of a low-stage hepatoblastoma detected by periodic surveillance with ultrasound in a patient at high risk of hepatoblastoma because of Beckwith-Wiedemann syndrome. The tumor was fully resected and classified as stage 1. *(Courtesy of Children's Medical Center, Dallas, Tex.)*

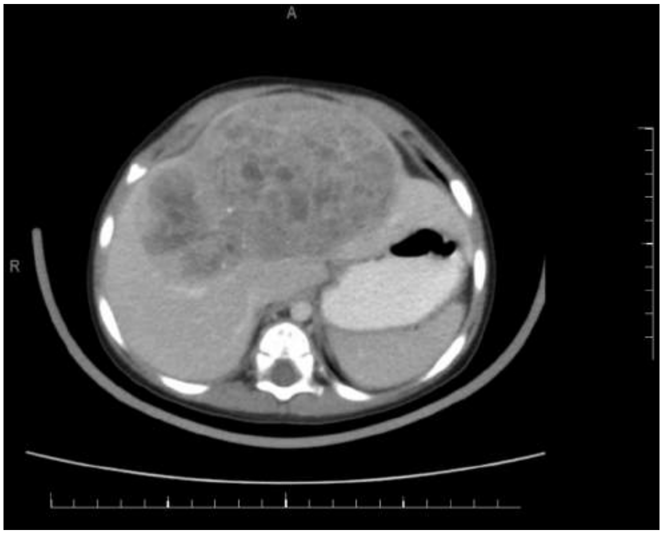

Figure 58-5 Computerized tomography of a high-stage hepatoblastoma. The tumor occupies most of the left lobe and a portion of the right lobe. Preoperative chemotherapy rendered this tumor resectable. This tumor was also accompanied by pulmonary metastases (not shown) and therefore was classified as stage 4 by North American staging system. *(Courtesy of Children's Hospital, Boston, Mass.)*

Both staging systems have been shown to have prognostic significance, but it is difficult to compare studies using different staging systems.[191] In the future the PRETEXT system will be used by most groups internationally.

PATHOLOGY OF HEPATOBLASTOMA AND HEPATOCELLULAR CARCINOMA

Grossly hepatoblastomas occur as single expansile masses, usually in the right lobe of the liver. A series of international discussions originating at the Los Angeles COG International Pathology Liver Tumors Symposium in 2011 resulted in a consensus classification of liver tumors in children, summarized in Table 58-3. A description of immunohistochemical properties currently recommended to aid in the classification of pediatric liver tumors is provided in Table 58-4.

A representative resected hepatoblastoma tumor is shown in Figure 58-6. Hepatoblastomas are composed primarily of epithelial cells that resemble different stages of the developing liver. Most hepatoblastomas are a mixture of cells resembling fetal cells and cells resembling embryonal cells. A typical hepatoblastoma of fetal and embryonal histology is shown in Figure 58-7, *A*. Because hepatoblastomas derive from immature cells that may retain the potential to differentiate, tumors often have foci of other types of more differentiated cells, including hematopoietic cells, as demonstrated in Figure 58-7, *B*. A subset of hepatoblastomas are characterized by cholangiocyte-like cells, which suggest the differentiation of the neoplastic cells along the cholangiocyte lineage as opposed to the hepatocyte lineage.[192] When the epithelial cells are aligned in thick cordlike structures, the tumor is described as having macrotrabecular features. In approximately 5% of hepatoblastomas, only fetal-type cells are seen histologically, as shown in Figure 58-7, *C*. These fetal-only tumors are now further classified according to the degree of mitoses.[3]

Two histologic subtypes of hepatoblastoma have significant implications for predicting clinical outcome. Approximately 7% of hepatoblastomas are composed of pure, well-differentiated fetal cells. The well-differentiated histology, previously referred to as *pure fetal histology*, has been associated with an exceptionally favorable outcome. A recent COG study by Malogolowkin and coworkers demonstrated that if the hepatoblastoma is completely resected surgically at the time of diagnosis, further therapy may be unnecessary.[193] The presence of this subtype and the desire to avoid the toxicity of

chemotherapy remain compelling reasons to pursue upfront resection whenever possible.

The small cell undifferentiated variant accounts for approximately 5% of hepatoblastoma and also carries clinical significance. Histologically the cells are small and pleomorphic and show high mitotic rates, as shown in Figure 58-7, *D*. There are several reports in small cell undifferentiated hepatoblastoma of unique chromosome translocations involving chromosome 22q12, the region of *SMARCB/INI1*, the gene most often associated with rhabdoid tumors and atypical teratoid tumors. Emerging evidence suggests that from histologic, cytogenetic, molecular genetic, and clinical perspectives these tumors resemble rhabdoid tumors to varying degrees.[194] Immunohistochemistry demonstrated loss of the INI1 protein in the small cell undifferentiated variant, and it is now recommended that INI1 staining be performed as part of the histologic characterization (see Table 58-4).[3] Mounting evidence suggests that the small cell variant is associated with a poor outcome.[188,194,195]

HCCs consist of cells that are well-differentiated and resemble normal hepatocytes. A typical HCC is shown in Figure 58-8. The fibrolamellar variant of HCC is characterized by larger, polygonal cells mixed with fibrous stroma and often eosinophilic cytoplasm, occasionally with cystic degeneration (Fig. 58-9).[196-198] In contrast to hepatoblastoma, the adjacent liver tissue in patients with HCC is often marked by cirrhosis. The fibrolamellar variant is an exception in which surrounding liver tissue is usually noncirrhotic.

ACQUIRED GENETIC CHANGES IN HEPATOBLASTOMA

Karyotypic changes in hepatoblastomas can be classified into two broad categories: numeric changes and structural changes of individual chromosomes, the most common of which involve translocations of chromosome

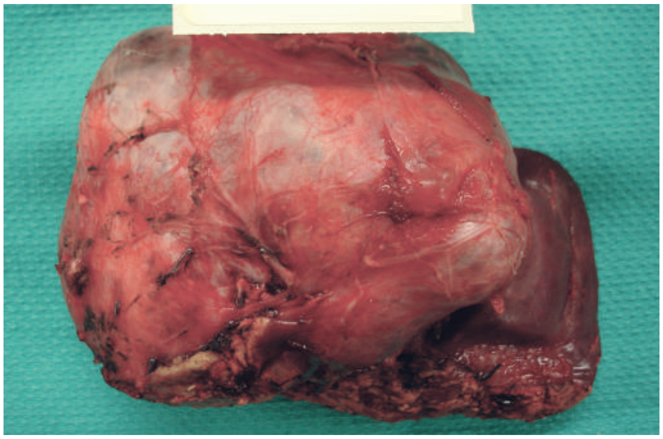

Figure 58-6 Gross pathology of resected hepatoblastoma tumor specimen. Tumor appears as a large expansile mass. The tumor has a whitish appearance compared with the darker adjacent liver in background. The cut surface is shown at the bottom of the image and has a variegated appearance. *(Courtesy of Victor Saldivar, MD, Children's Hospital of San Antonio, Tex.)*

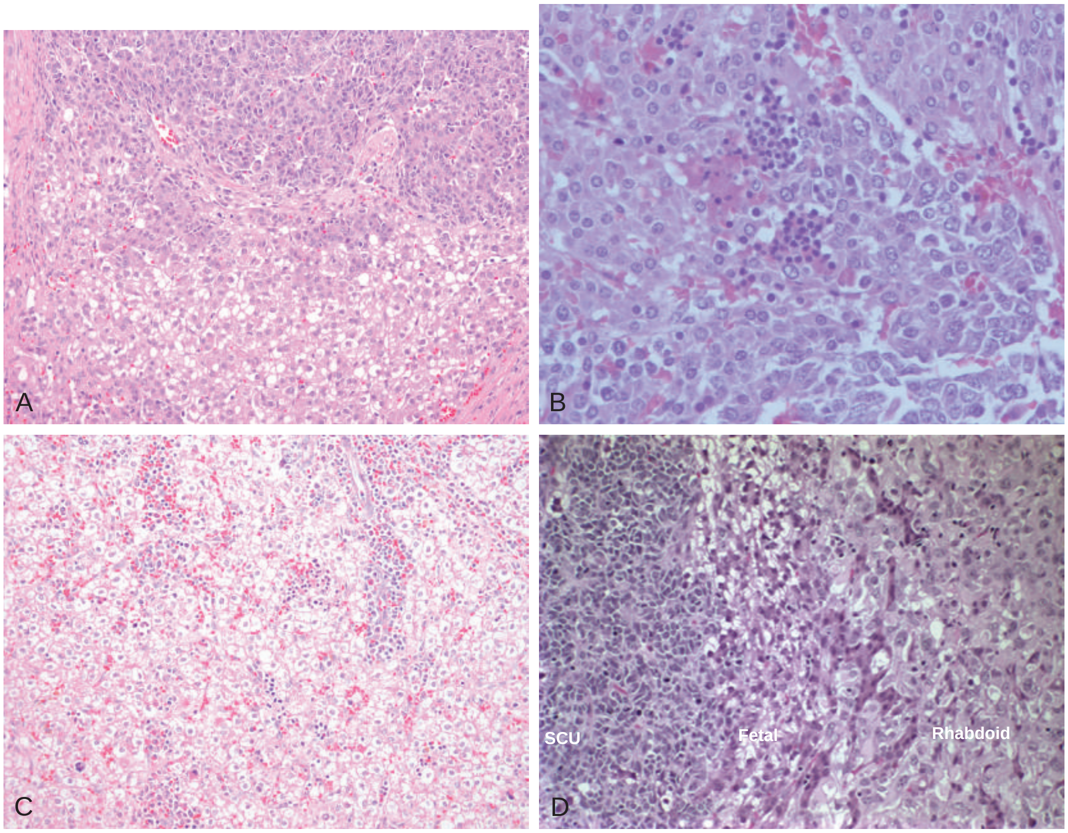

Figure 58-7 **A,** Mixed fetal and embryonal epithelial hepatoblastoma. This hepatoblastoma shows two different morphologic patterns. The fetal pattern, seen in the lower part of the image, is composed of uniform, small cuboidal cells with distinct cell membranes, whereas the embryonal pattern, seen in upper part of the image, consists of smaller angulated cells with hyperchromatic nuclei, higher nuclear-to-cytoplasmic ratios, and indistinct cell membranes. This is the most common histologic pattern of hepatoblastoma. **B,** Hepatoblastoma with extramedullary hematopoesis. As is often observed in hepatoblastoma, islands of hematopoietic cells are observed as clusters of small dark cells with prominent nuclei within surrounding tumor tissue. **C,** Pure fetal epithelial hepatoblastoma. This is composed of relatively uniform, small cuboidal cells. The cells have a small round nucleus with inconspicuous nucleolus, abundant cytoplasm that may be clear or finely granular, and distinct cell membranes. The pure fetal variant accounts for approximately 5% of all hepatoblastomas and is associated with a favorable outcome. **D,** Small cell undifferentiated hepatoblastoma. The central portion shows cells resembling fetal hepatoblastoma. On the *left,* cells appear undifferentiated with round nuclei and minimal cytoplasm and fail to form tubules. At *right,* cells are more typical of rhabdoid-like histology. *(**A**, Courtesy of Dinesh Rakheja, MD, Children's Medical Center, Dallas, Tex.; **B**, Courtesy of Victor Saldivar, MD, Children's Hospital of San Antonio, Tex.; **C**, Courtesy of Dinesh Rakheja, MD, Children's Medical Center, Dallas, Tex.; **D**, Courtesy of Milton Finegold, MD, Texas Children's Hospital, Houston, Tex.)*

1.[114] The initial recurring translocation described was the translocation involving chromosomes 1 and 4, t(1;4)(q12;q34).[199,200] It has since been reported in a large series that hepatoblastoma is characterized by a family of chromosome translocations with similar breakpoints on either chromosome 1q12 or 1q21.[114] Each such translocation observed is unbalanced, resulting in a gain of the long arm of chromosome 1, and is also frequently associated with numerous whole chromosomal gains.

Most of the numeric aberrations result in addition of whole chromosomes, but occasionally they result in loss of chromosomes. The specific numeric changes are nonrandom. Trisomies of chromosome 2, 8, and 20 are the most common recurring numeric aberrations. The most commonly observed chromosomal losses are chromosomes 4 and 18. Although these whole chromosome changes have been described previously by classical karyotype analysis, they can perhaps be better visualized by whole genome comparative genomic hybridization, as shown in Figure 58-10. The clinical significance of these chromosomal abnormalities is not yet known..

HCC is also characterized also by chromosomal gains and losses, with loss of the Y chromosome a notable finding.[201] Duplication of chromosome 1q is also seen in HCC with increased expression of numerous chromosome 1 genes.[202,203] Cytogenetic data on the fibrolamellar variant of HCC is sparse, but one childhood fibrolamellar carcinoma has been characterized by a hypertriploid karyotype with clonal evolution and multiple additional chromosomal gains as well as loss of the Y chromosome.[204]

MOLECULAR ABERRATIONS

The most common genetic alteration in hepatoblastoma is alteration of the Wnt signaling pathway. *CTNNB1* alteration is detected in the vast majority of hepatoblastomas, either as a point mutation in exon 3 or a large gene deletion.[205,206] Less commonly alterations are observed in other members of the Wnt signaling pathway, including *APC* and *AXIN* genes.[207] CTNNB1 accumulates in the nucleus of tumor cells with alterations of the Wnt signaling pathway.

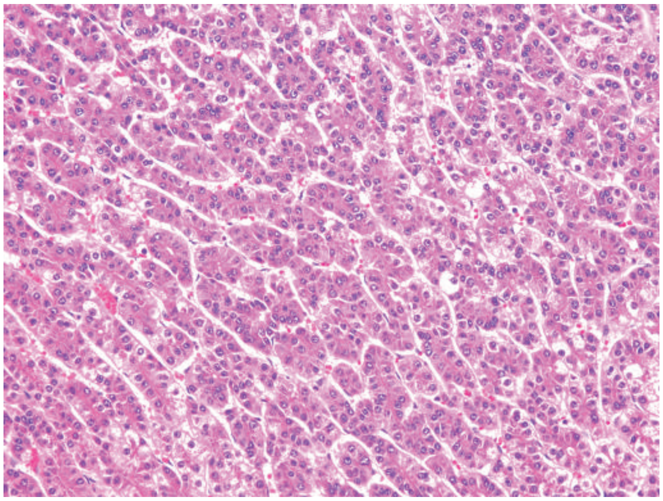

Figure 58-8 Hepatocellular carcinoma. This well-differentiated hepatocellular carcinoma is composed of two- to four-layer thick cords or trabeculae of cells resembling normal hepatocytes. Sinusoidal-like spaces lined by endothelial cells are present between the trabeculae, further mimicking the architecture of normal liver. No portal tracts are present. *(Courtesy of Dinesh Rakeja, MD, Children's Medical Center, Dallas, Tex.)*

In a preliminary whole exome study by Trevino and colleagues, mutation of the *NFE2L2* gene was present in approximately 6% of hepatoblastoma tumors.[208] Of note this same gene mutation is observed in 6% of HCCs in adults.[209]

Cairo and coworkers have demonstrated that upregulation of MYC in conjunction with Wnt signaling aberration is a hallmark of aggressive hepatoblastoma and have described a 16-gene signature in a posttreatment resected specimen that was associated with a more aggressive clinical behavior.[210] These and other molecular findings will need to be examined in a prospective study to determine the impact on patient risk stratification and management.

TREATMENT: CHEMOTHERAPY IN HEPATOBLASTOMA

Chemotherapy has been used extensively in the management of hepatoblastoma to reduce tumor bulk and thereby render tumors resectable and to treat microscopic disease after resection. Surgical resection, as discussed later, is essential for all malignant liver tumors to achieve cure. Although great strides have been made in the development of chemotherapeutic approaches for hepatoblastoma, challenges remain in eradicating unresectable disease as well as in determining new effective agents for refractory disease. Success in the past three decades has been obtained primarily through the four major cooperative groups based in North American (COG and its predecessors), Europe (SIOPEL), Germany (Cooperative German Paediatric Liver Tumor Study), and Japan (Japanese Study Group for Pediatric Liver Tumor [JPLT]). The legacy North American cooperative group approach has been to resect, if possible, before the administration of chemotherapy, whereas the European approach has been to use neoadjuvant chemotherapy with initial biopsy to shrink tumors before therapy. Regimens used in the treatment of hepatoblastoma have centered largely on platinum agents and doxorubicin. Other agents studied and incorporated into protocols have included vincristine, 5-fluorouracil, ifosfamide, etoposide, and recently irinotecan. A summary of results of published treatment regimens is given in Table 58-5.

Early reports documented the effectiveness of vincristine as a single agent,[211,212] and subsequent Pediatric Oncology Group and Children's Cancer Group trials used vincristine along with 5-fluorouracil and cisplatin. Doxorubicin was shown to be effective in a phase II trial of refractory pediatric solid tumors, including hepatoblastoma, using either a 4-day course of 15 to 20 mg/m^2 daily or a 3-day course of 30 mg/m^2 daily.[213]

A study from St. Jude Children's Research Hospital reported a response to cisplatin (DDP) at a dose of

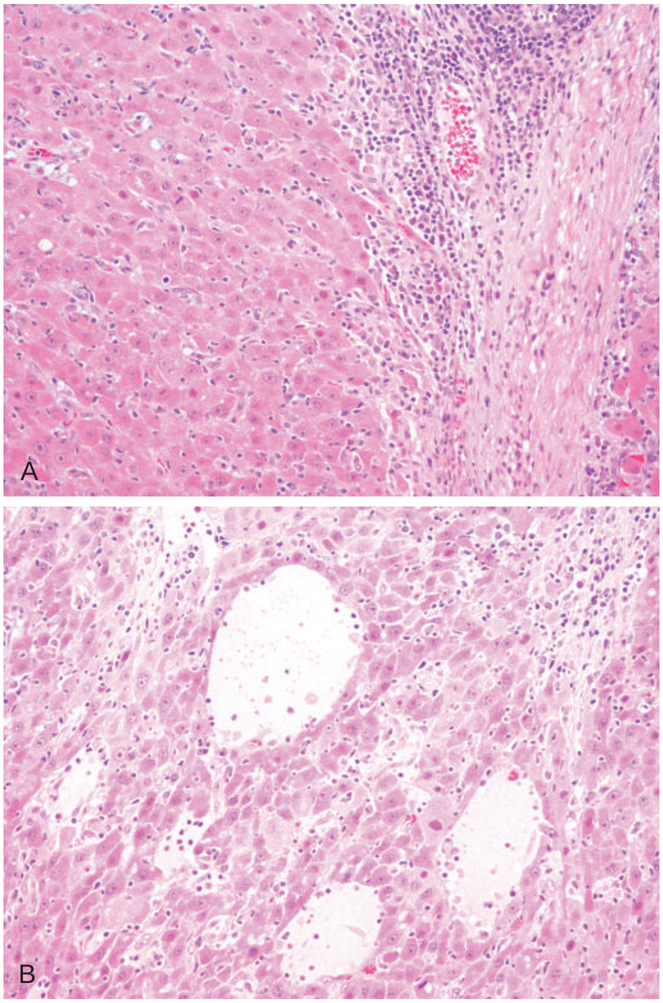

Figure 58-9 Fibrolamellar hepatocellular carcinoma. Fibrolamellar hepatocellular carcinoma is composed of sheets of polygonal tumor cells that are larger than normal hepatocytes and have a deeply eosinophilic cytoplasm, a large nucleus with prominent eosinophilic nucleolus. As shown prominently in **A,** the cells are embedded in collagenous stroma, and variably thick fibrous septa course through the tumor. Often there are focal infiltrates of mononuclear inflammatory cells. **B,** Foci of cystic degeneration (pseudogland formation) are apparent. *(Courtesy of Dinesh Rakeja, MD, Children's Medical Center, Dallas, Tex.)*

TABLE 58-5 A Summary of Recent Cooperative Group Studies in Europe and North America

Study Protocol	Presurgical chemotherapy	Chemotherapy agents	N =	Outcome	Reference
POG—#8697	No	Cisplatin, vincristine, fluorouracil (C5V)	73	3-year EFS: stage I (UH) / II: 91% stage III: 67% stage IV 12.5%	305
COG—#9645	Yes	C5V vs. intensified platinum[*]	33	5-year EFS: stage III: 73% stage IV: 27%	306
INT—0098	Selected patients	C5V vs. cisplatin and doxorubicin	182	5-year EFS: stage I (UH) / II: >90% stage III/IV: >50%	4
HB—89	Yes	Ifosfamide, cisplatin, doxorubicin	72	3-year EFS: stage I: 100% stage II: 50% stage III: 74% stage IV: 29%	225
HB—94	Selected patients	Ifosfamide, cisplatin, doxorubicin	69	3-year EFS: stage I: 96% stage II: 100% stage III: 76% stage IV: 36%	226
SIOPEL—1	Yes	cisplatin, doxorubicin	154	5-year OS: 75%	222
SIOPEL—2	Yes	Cisplatin/carboplatin, doxorubicin—risk stratified	150	3-year OS[†] SR: 90% HR: 78%	7
SIOPEL—3	Yes	Cisplatin/ carboplatin	151 (HR)[‡]	3-year OS: 69% (HR)	223
SIOPEL—4	Yes	Cisplatin—dose dense	61 (HR)	3-year OS = 83% (HR)	224

COG, Children's Oncology Group; *EFS,* event-free survival; *HR,* high risk; *OS,* overall survival; *POG,* Pediatric Oncology Group; *SIOPEL,* Childhood Liver Tumours Study Group; *SR,* standard risk; *UH,* unfavorable histology.

[*] Only Stage II and IV patients enrolled.

[†] SR: Standard risk. Defined as hepatoblastoma confined to the liver and involving no more than three hepatic sectors.

[‡] HR: High risk. Defined as hepatoblastoma extending into all four sectors or lung metastases or extrahepatic involvement (or a combination thereof).

90 mg/m^2 in 10 of 11 patients with hepatoblastoma.[214] A subsequent study at MD Anderson Cancer Center used high-dose cisplatin (150 mg/m^2 as a single dose) in patients with unresectable hepatoblastoma, showing a marked response in primary tumor size as well as metastatic disease.[215] Platinum compounds subsequently emerged as the most effective means to treat hepatoblastoma, although treatment has been associated with considerable toxicity. Ototoxicity was observed in 37% of children receiving platinum agents, according to a European study that included 120 children with cancer diagnosed at a median age of 2.6 years, including 11 patients with hepatoblastoma; the ototoxicity was most severe in patients younger than 36 years of age at diagnosis and was progressive over time.[216]

The use of doxorubicin and cisplatin together in the treatment of hepatoblastoma has long been shown to be effective. The first report of this combination described a 15-month-old girl with unresectable hepatoblastoma of mixed histology who received doxorubicin and cisplatin.[217] Quinn and colleagues reported four patients with hepatoblastoma, three of whom had unresectable tumors that were treated with cisplatin and doxorubicin.[217a]

The successful combination of cisplatin with doxorubicin was further studied in Toronto. In this study 15 children were treated with cisplatin (20 mg/m^2 daily for 5 days) in combination with doxorubicin (25 mg/m^2 daily for 3 days), with unresectable disease in 13 of the original 15.[8] A second report, also from Toronto, documented success in administering similar doses of cisplatin and doxorubicin simultaneously as a continuous infusion in an attempt to further increase cell kill while minimizing toxicity.[218] Significant tumor reduction allowing surgical resection was attained in all six of the patients studied, with five surviving over the long-term and one child dying perioperatively as a result of surgical complications.

The Children's Cancer Study Group undertook a study administering cisplatin at a dose of 100 mg/m^2 daily together with continuously infused doxorubicin and reported efficacy in initially unresectable hepatoblastoma.[219] Building on this successful combination of doxorubicin and cisplatin, the two North American cooperative groups designed an intergroup study to determine the efficacy and safety of this regimen in a large number of patients. The doxorubicin and cisplatin regimen was

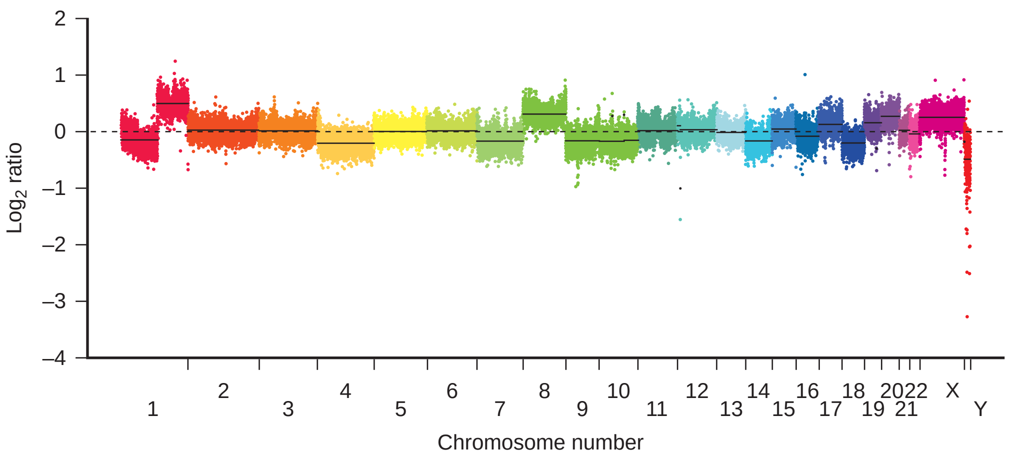

Figure 58-10 Genome-wide copy number comparative genomic hybridization (CGH) scan of hepatoblastoma tumor compared with standard normal male control DNA. Hepatoblastoma is characterized by whole chromosome gains and losses as well as unbalanced translocations of chromosome 1 resulting in duplication of the long arm of chromosome 1q. This CGH plot demonstrates increased copy number of chromosome 8, 17, 19, and 20 as well as whole chromosome losses of chromosomes 4 7, 9, 10, 14, and 18. In addition a duplication of chromosome 1q and loss of chromosome 1p is observed. Numeric aberrations of X and Y reflect the female sex of the child rather than tumor-specific changes.

found to be as effective as the cisplatin, vincristine, and 5-fluorouracil regimen (C5V); however toxicity was greater, particularly in infants, in the patients treated with the doxorubicin and cisplatin regimen.[4] Subsequent studies in North America have omitted doxorubicin and concentrated on platinum-based regimens.

The use of alternating platinum analogues cisplatin and carboplatin without concomitant use of other agents was attempted in a randomized trial conducted by the Pediatric Oncology Group P9645, but this resulted in a dismal outcome of a 37% event-free survival rate compared with a 57% event-free survival rate for patients receiving the C5V regimen. In addition, patients randomized to receive intensified platinum therapy only experienced more toxicity and a greater need for transfusions. Therefore the standard of care in North America returned to the C5V regimen, with the recent trials (AHEP0731) re-incorporating the use of doxorubicin in addition to C5V in intermediate-risk patients. This trial also explored the efficacy of irinotecan as an upfront window in the patients at highest risk.

Because early reviews suggested that tumors of pure fetal histology had a more favorable outcome,[220,221] a concentrated effort has been made to reduce therapy in this group. The first attempt to reduce therapy in this subset of tumors was in the intergroup study POG 8945/CCG 8881, in which patients with stage 1 tumors of pure fetal histology were treated with four courses of doxorubicin only, compared with patients with other tumors, which were treated with multiagent therapy. In the recent AHEP0731 study, tumors of pure fetal histology, if fully resected, received no further therapy. The ability to avoid chemotherapy in this select group of tumors, based on pathology, argues strongly for the need for histologic characterization before embarking on any course of chemotherapy.

The Europe-based SIOPEL group also used a regimen of cisplatin and continuous infusion of doxorubicin in the SIOPEL-1 study, with 5-year survival rates of PRETEXT I, II, III, and IV disease observed to be 100%, 83%, 56%, and 46%, respectively.[222] SIOPEL-2 used cisplatin for standard-risk patients and cisplatin alternating with carboplatin and doxorubicin in higher-risk patients.[7] SIOPEL-3 demonstrated notable improvement in patients with metastatic disease, with a 5-year survival rate of 56% following intensive treatment of 10 cycles of cisplatin alternating with carboplatin and doxorubicin.[223] The recent SIOPEL-4 study used a dose-dense cisplatin-based regimen that also included doxorubicin for high-risk patients (i.e., those with extrahepatic abdominal disease, major vascular invasion, tumor rupture, tumor in all segments, or metastatic disease). The overall survival rate at 3 years was 83%, a significant improvement over past regimens; however moderate to severe ototoxicity occurred in 50% of patients.[224] Given the efficacy of cisplatin along with the frequent occurrence of ototoxicity now documented in multiple studies, families of children currently treated for hepatoblastoma should be advised of the risk of hearing loss, and children should be closely monitored during treatment and for years afterward. A current priority is the development of therapies that are less toxic.

Exploration of treatment by the German cooperative groups has included the use of ifosfamide in conjunction with cisplatin and doxorubicin (IPA). The overall survival rate was 75%, which is comparable to that of SIOPEL and North American studies and indicates a possible alternative approach. However the combination of etoposide, ifosfamide, and carboplatin used in stage IV tumors had a survival rate of 21%, a dismal result similar to those of previous regimens.[225,226]

Treatment of Recurrent or Refractory Disease

Despite the often successful treatment of newly diagnosed hepatoblastoma, treatment of recurrent hepatoblastoma remains a significant therapeutic challenge. The relative rarity of tumor recurrence poses additional challenges to retrieval protocol development strategies. As with the treatment of primary disease, the ability to surgically resect recurrent disease may influence outcome, and surgical approaches to recurrent disease either for local hepatic recurrence or for pulmonary metastases have met with some success.

Feusner et al reported in 1993 from the early Children's Cancer Group study CCG-881 that of 10 initially low-stage hepatoblastoma tumors that later recurred with lung metastases, the most effective treatment was surgical resection of metastatic lesions in addition to systemic chemotherapy.[227] In a retrospective study by Meyers and colleagues of 20 patients with initial clearance of pulmonary disease, using INT-0098 data, 13 had a surgical approach, with 4 of 13 surviving.[228] These studies suggest that surgical resection may play a role in survival, but they also underscore the need for better systemic therapies to control metastatic disease. The SIOPEL group reported 59 patients from SIOPEL studies 1,2, and 3.[229] All of these patients received doxorubicin as part of their initial therapy. Retrieval strategies were attempted in 52 patients and varied, including chemotherapy plus surgery in 25 (42%), chemotherapy alone in 21 (36%), and surgery alone in 7 (12%). Palliative care only was provided in five cases. Slightly more than half of the patients achieved a second complete response, but the 3-year event-free survival rate was only 34 %. Factors associated with successful outcome included PRETEXT group I through III at diagnosis and the use of both surgery and chemotherapy as a retrieval strategy.

High-dose chemotherapy with stem cell rescue has been attempted for hepatoblastoma with little success, as summarized elsewhere.[230] The Japanese Study Group for Pediatric Liver Tumor, JPLT-2, has also reported limited success with high-dose chemotherapy and stem cell transplant.[231]

TREATMENT OF HEPATOCELLULAR CARCINOMA

Compared with the successes in treating hepatoblastoma with chemotherapy, the progress in treating HCC has been for the most part disappointing in both children and adults. Although an early study indicated that doxorubicin induced remission in HCC in 14 of 44 (32%) patients[232] subsequent studies with doxorubicin in HCC have been disappointing. Within the cooperative groups, because of the small numbers seen, HCC has been treated similarly to hepatoblastoma, with acknowledgment that it is a distinct entity. Survival for initially unresectable HCC has remained dismal. When patients treated with regimens of cisplatin, vincristine, and 5-fluorouracil were compared to patients treated with continuously infused cisplatin and doxorubicin using the same regimens shown to be effective in hepatoblastoma[4] the results demonstrated that less than 20% of stage III and IV patients survived.[37] However among eight patients with HCC that was resected at diagnosis, the long-term survival rate was 88%. This is the largest treatment study of HCC in children. Thus early resectability is an important factor in predicting the likelihood of survival in children who have HCC, which is similar to that observed in adults with HCC.

In 2007 the FDA approved the use of sorafenib, an oral tyrosine kinase inhibitor previously shown to be effective in treating advanced renal cell carcinoma, in the treatment of HCC after a large trial of 602 adult patients demonstrated a median 10.7-month survival rate and a 5.5-month time to tumor progression in patients treated with 400 mg sorafenib twice daily compared with a median 7.9-month survival rate and 2.8-month time to tumor progression in patients treated with placebo. The dose-limiting toxicity of sorafenib appears to be hand-foot skin reaction with other toxicities, such as diarrhea and lipase or amylase elevation. A previous recent study in the United States, from Memorial Sloan Kettering, demonstrated in a phase II, nonrandomized study that sorafenib was well-tolerated, albeit with a modest efficacy, which would suggest an indication for its future inclusion in multiagent trials for HCC.[233] Interestingly this study also performed gene expression microarray analysis on tumors treated with sorafenib and placebo and determined a pattern of gene expression that correlated with a response to sorafenib; this information could conceivably serve as a means of treatment stratification in future trials. Further exploration of the role of sorafenib in pediatric liver tumors is warranted.

SURGICAL ASPECTS OF LIVER TUMORS

Surgical resection is an important component in the management of both benign and malignant liver tumors. In the case of benign lesions such as adenoma, focal nodular hyperplasia, and mesenchymal hamartoma, complete resection of the tumor is usually curative. Resection may involve anatomic lobectomy when necessary or nonanatomic wedge resection in the case of smaller peripheral lesions. In the case of hemangiomas or other vascular malformations of the liver, specific diagnosis is essential to avoid unnecessary surgical intervention or inappropriate use of steroids or chemotherapy agents.[234]

In the assessment of hepatoblastoma for resectability, a high-quality computed tomography (CT) scan or magnetic resonance imaging (MRI) is essential, especially in the adoption of the PRETEXT staging system, which relies on presurgical imaging.[235-238] These studies should be performed with particular attention to the vascular anatomy of the liver. A dual-phase CT scan with both arterial and venous phases may be used to assess vascular involvement and resectability. MRI, sometimes supplemented with magnetic resonance angiography, provides an excellent depiction of vascular anatomy.[238]

Although the PRETEXT staging system is a useful guide for deciding whether a lesion is resectable, the ultimate decision regarding surgical management rests with the surgeon. If possible primary resection should be undertaken for PRETEXT I or II tumors if there is no vascular involvement. Involvement of all three hepatic veins or both branches of the portal vein will usually preclude surgical resection. However a PRETEXT III or IV lesion that appears unresectable at the time of diagnosis may respond very well to chemotherapy, and repeat imaging after two or three cycles of chemotherapy might demonstrate adequate regression of the tumor from vital vascular structures, enabling resection. Very rarely will arterial or biliary involvement preclude tumor resection. In some cases of extensive tumor involving the bifurcation of the bile ducts, biliary reconstruction may be necessary. At the time of surgical resection, any suspicious porta hepatis, hepatic artery, celiac, or periaortic lymph nodes should be sampled. When complete tumor resection is not feasible despite adequate chemotherapy, liver transplantation should be performed.[239-242] Therefore early referral of patients with PRETEXT III or IV tumors to a center that performs liver transplantation is essential.

Surgery remains the mainstay of treatment for HCC given the poor response to chemotherapy and other modalities, including chemoembolization, radiofrequency ablation, and cryotherapy. When HCC develops in the context of cirrhosis, surgery may be limited by the lack of liver physiologic reserve.[243] In these cases transplantation may be the only safe option even for early-stage disease. In the fibrolamellar variant, the remaining adjacent liver is usually normal and therefore resection is more often possible even with extensive disease; this may be a factor contributing to the impression that fibrolamellar HCC has a better prognosis than standard HCC, although stage for stage, fibrolamellar HCC is not different from other types of HCC and depends on resectability for cure.[39,244] Other malignant tumors of the liver, including angiosarcoma, embryonal sarcomas, rhabdoid tumors, and rhabdomyosarcoma, like other malignant liver tumors, require complete resection if there is to be any hope for cure.[245-255]

Transplantation has become increasingly common in the treatment of unresectable hepatoblastoma. In most cases involving malignant liver tumors, complete surgical resection is a necessary component of therapy. Whether benign or malignant, when complete surgical resection by way of partial hepatectomy is not possible because of the extent of disease or lack of hepatic reserve, liver transplantation is the only remaining option. Approximately 2% of children undergoing liver transplants received the livers as treatment for hepatoblastoma,[256] although clearly this number is increasing in recent years. Although liver transplantation for malignant disease was used during the early years of liver transplantation, the survival rate was poor because of transplantation complications as well as recurrent disease. More recent data demonstrate significantly improved survival rates in select patients after transplantation to treat both hepatoblastoma and HCC.[257,258-262] The combined experience of SIOPEL studies was quite favorable: 25 patients with otherwise unresectable hepatoblastoma confined to the liver underwent transplantation after chemotherapy, with the survival rate for patient and graft at 100% after 1 year for living related donor transplants (N = 7) and 91% for cadaveric transplants (N = 18). At 10 years after transplant, the survival rate was 77.6% for cadaveric transplants and 83% for living related donor transplants.[263] In a recent overview of SEER data involving patients younger than 20 years of age undergoing surgery for hepatoblastoma, of a total of 318 patients with hepatoblastoma, 16.7% underwent transplant; of 80 patients with HCC, 25% underwent transplant. The survival rate at 5 years was 86.5% for hepatoblastoma and 85.3% for HCC.[264] PLUTO (Pediatric Liver Unresectable Tumor Observatory) is an international registry established to capture data, including detailed clinical parameters and outcome statistics, and will be a source of additional information on transplantation of pediatric liver tumors.[265]

In the planning of therapy for patients with advanced hepatoblastoma that may require liver transplantation, early referral to a liver transplant center is key. Options for transplantation include the more traditional deceased donor whole organ or donor split liver transplants and also, more recently, living-donor transplants.[256] Although there are no data to suggest optimal timing for transplantation, most centers will administer at least two rounds of chemotherapy before transplantation in an attempt to shrink the tumor and determine whether resection without transplantation may be an option. Given the small window of opportunity to perform a transplant between cycles, close communication between the oncology team and the transplant team is critical. Evaluation by an experienced transplant team should take place as soon after diagnosis as possible. Current United Network for Organ Sharing (UNOS) liver allocation policy prioritizes children who require liver transplantation for hepatoblastoma. A child listed for transplantation with a diagnosis of hepatoblastoma is automatically assigned 30 PELD (Pediatric End-Stage Liver Disease) points, with the opportunity to be upgraded to status 1B after 30 days. This high priority listing allows patients a reasonable chance of receiving transplants between cycles when hematologic counts are not prohibitive. In the case of living-donor transplantation, the surgery can be scheduled electively. At the time of transplant an initial early abdominal exploration to rule out metastatic disease is required. If intraabdominal metastatic disease is discovered and is not completely resectable, transplantation should be aborted.

Liver transplantation for HCC has evolved significantly over the past several years, and as stated previously, SEER data indicate an 85% 5-year survival rate for HCC patients younger than 20 years undergoing liver transplantation.[264] Centers have used the Milan criteria to select patients for liver transplantation; these criteria allow for increased MELD (Model for End-Stage Liver Disease) points in patients with stage II disease.[260] However data from the University of California San Francisco (UCSF) group demonstrate acceptable patient survival rates after transplantation for patients who exceed the Milan criteria, generally established for adult patients.[266]

LESS COMMON MALIGNANT TUMORS OF THE LIVER

Embryonal sarcoma of the liver, also termed *undifferentiated embryonal sarcoma of the liver* (UESL), is the third most common malignant liver tumor in children.[100] UESL was first recognized as a distinct entity in 1978.[267] Histologically these tumors are composed of mixtures of cells with histiocytoid, fibrohistiocytoid, myofibroblastic, and undifferentiated (primitive mesenchymal) morphologies.[268] They share a chromosome translocation similar to that seen in mesenchymal hamartoma (discussed later) and are thought to arise from the benign mesenchymal hamartoma as a malignant counterpart.[252,269-273] UESL can be distinguished from biliary tract rhabdomyosarcomas by several immunohistochemical stains, including myogenin and MyoD1, which are negative in UESL and positive in rhabdomyosarcoma.[274] UESL differs from rhabdomyosarcoma of the liver in that the median age of UESL is 10.5 years, compared with 3.6 years for rhabdomyosarcoma.

The male-to-female ratio in UESL is 1:1. USEL is considered an aggressive malignancy that should be treated with multiagent regimens used for soft tissue sarcomas of other sites.[275] A European Cooperative Group study from Italy and Germany treated a series of 17 patients with UESL with chemotherapy, conservative surgery, and (in two patients) radiotherapy. Of the 17 patients 12 survived (70%), and all of those who underwent complete resection survived.[276] A more recent series reported 10 patients with UESL, all receiving both combination chemotherapy and surgery, three with upfront resection, and seven with resection after neoadjuvant chemotherapy. Nine of the ten (90%) survived.[277]

True rhabdomyosarcomas, when they are seen in the hepatobiliary system, occur in the biliary tract. These tumors are mesenchymal in origin and histologically resemble rhabdomyosarcomas of other sites with prominent myoblastic cells that stain for myogenin.[274] The tumors may have a botryoid appearance.[278,279] Obstructive jaundice is the usual presenting sign, with or without abdominal distention.[279,280] In an early report from the Intergroup Rhabdomyosarcoma Study, only 4 of 10 patients with biliary tract tumors survived.[280] However additional reports cite better long-term survival rates with chemotherapy regimens and without the need for extensive surgery.[281,282]

Angiosarcomas of the liver are rare but aggressive high-grade malignancies derived from endothelial cells.[246,248,283] Angiosarcoma of the liver in children was previously known as *infantile hemangioendothelioma type 2*.[284] Fewer than 40 cases have been reported. Some cases have been preceded by a diagnosis of infantile hepatic hemangioendotheliomas.[246,285,286] In contrast to other malignant liver tumors in children, angiosarcomas are more common in girls than boys. The pathology of pediatric angiosarcoma is distinct from angiosarcomas in adults in that kaposiform spindle cells are present. The overall prognosis is poor.[246] Although liver transplantation had been reported as successful in one child, a recent European study indicated an overall exceptionally poor outcome in a series of angiosarcomas after liver transplantation.[287,288]

Choriocarcinoma of the liver is an extremely rare tumor. Most cases of infantile choriocarcinoma are actually metastases from gestational choriocarcinoma of the placenta that spreads to the child; however, primary tumors of the liver have been reported. This can be an aggressive and devastating tumor, and although the overall outcome has been historically poor, there are recent reports of cures with chemotherapy, including one case with liver transplant.[289-292] Other primary germ cell tumors of the liver have been reported but are extremely rare.[293]

BENIGN TUMORS OF THE LIVER

Hepatic mesenchymal hamartoma (HMH) is a benign tumor with an age distribution similar to hepatoblastoma, with almost all cases occurring by 5 years. Patients with these tumors present with an enlarged abdomen. Clinical presentation can resemble that of hepatoblastoma, although the serum AFP level is not elevated.[294] As with hepatoblastoma, the majority of HMHs arise in the right side of the liver. HMHs are characterized by the presence of cysts, which are less characteristic of hepatoblastoma. Figure 58-11 demonstrates the cystic appearance on imaging. These benign tumors are characterized by massive growth and cause morbidity by compressing adjacent structures. Occasionally these tumors are diagnosed prenatally and can be a cause of fetal demise.[294] Microscopically HMH consists of spindle cells in a myxoid background with occasional areas of extramedullary hematopoiesis similar to that seen in hepatoblastoma. Figure 58-12 demonstrates the histologic pattern characteristic of HMHs with fluid-filled cystic areas. Cytogenetically these tumors are characterized by translocations involving 19q13.4, as described in multiple cases.[252,271,295-297] The breakpoints involved in one such translocation have been characterized.[273] An interstitial deletion at 19q13.4 has also been reported.[298] HMH can show malignant transformation into malignant mesenchymoma or embryonal sarcoma.[270,299] Treatment of HMH is usually surgical removal. Long-term follow-up of patients after resection is generally favorable.[300]

Hemangioendothelioma is a term that has been used to denote a type of benign vascular tumor. Previously

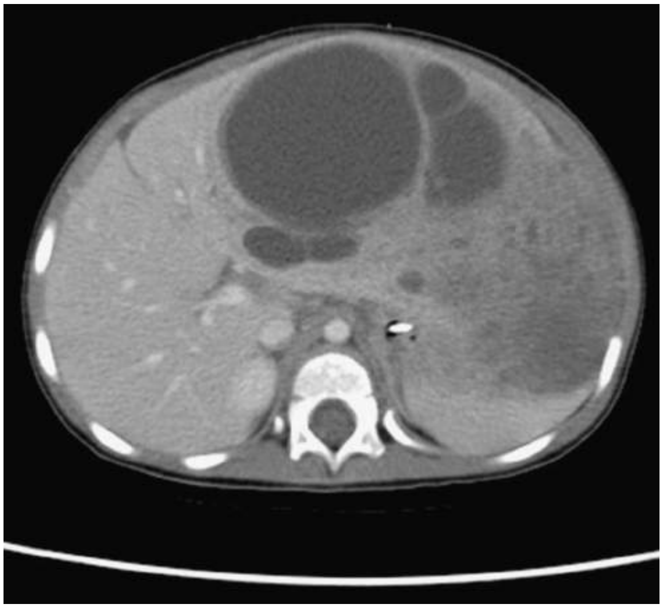

Figure 58-11 Computerized tomography image of an child with mesenchymal hamatoma. Note the multiple cysts with little solid component.

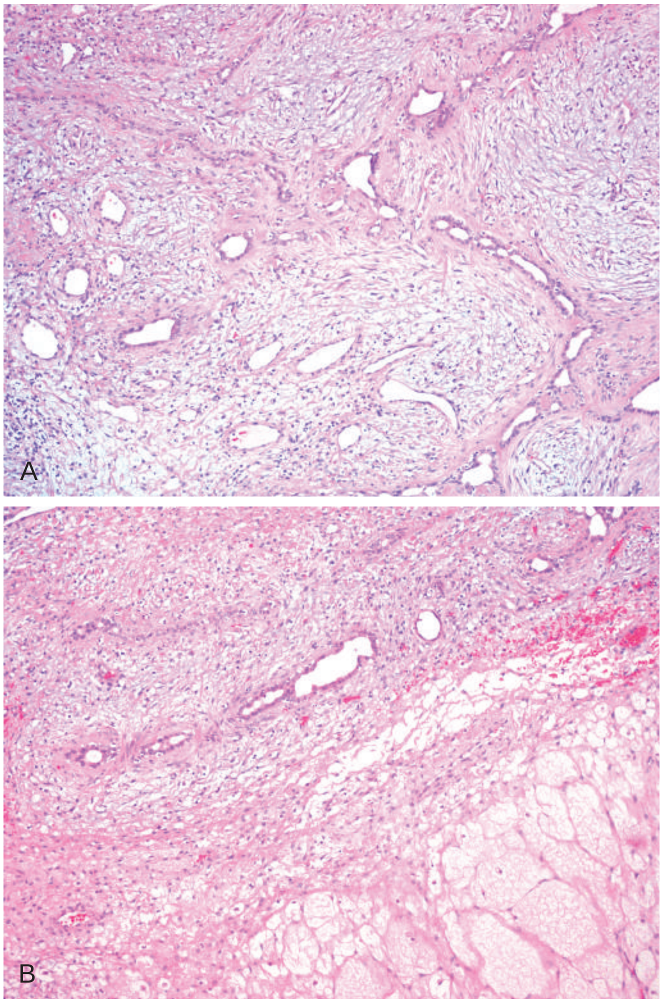

Figure 58-12 Mesenchymal hamartomas. Mesenchymal hamartoma is composed of haphazardly arranged and architecturally distorted elements that are normally found in the liver. In **A,** dilated and serpentine biliary ducts, each surrounded by a variably thick cuff of collagen, are apparent. The bile ducts are lined with low cuboidal epithelial cells without cytologic atypia. The second image (**B**) also shows fluid-filled lymphatic-like cystic spaces. All of these elements are embedded in a myxoid and edematous mesenchyme containing delicate fibroblasts. *(Courtesy of Dinesh Rakheja, MD, Children's Medical Center, Dallas, Tex.)*

grouped together as *infantile hepatic hemangioendothelioma,* the pediatric benign hepatic vascular tumors have recently been shown to be at least two different lesions—hepatic infantile hemangioma and congenital hepatic vascular malformation with associated capillary proliferation. One type (infantile or juvenile hemangioma) often manifests as multiple masses that usually involute and regress. The other type, which has been called a vascular malformation, is usually a large single mass that often undergoes central infarction, does not regress, and may be associated with consumption coagulopathy caused by platelet trapping in the abnormal vasculature. GLUT1 endothelial reactivity distinguishes the two entities histologically, with hepatic infantile hemangiomas staining positively for GLUT1 whereas the hepatic vascular malformations do not exhibit GLUT1 immunoreactivity.[301] Figure 58-13 demonstrates these two benign hepatic vascular disorders. Patients with hepatic hemangioendothelioma usually exhibit abdominal enlargement with or without congestive heart failure. Hemangioendothelioma may be distinguished from hepatoblastoma by imaging studies, particularly Doppler flow studies.[302] Many hepatic hemangioendotheliomas involute without intervention. Although steroids have been used in the past, propranolol has been used successfully to treat some hemangiomas of the liver, although the precise indications for its use have not yet been well-defined.[303,304]

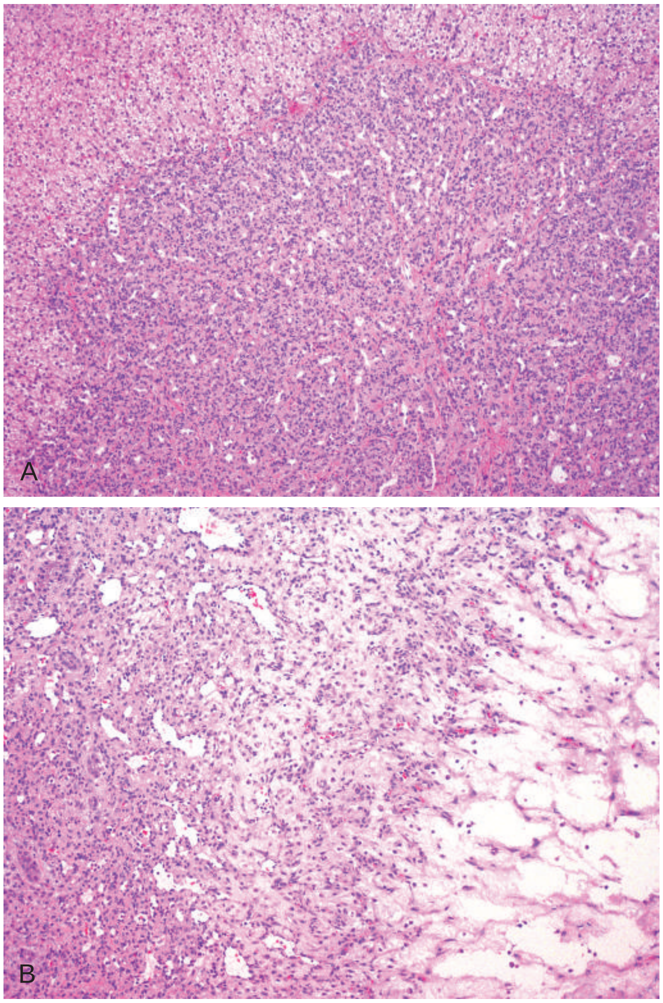

Figure 58-13 Benign hepatic vascular tumors. Previously grouped together as infantile hepatic hemangioendothelioma, the pediatric benign hepatic vascular tumors have recently been identified as at least two different lesions. Hepatic infantile hemangioma can be distinguished from congenital hepatic vascular malformation with associated capillary proliferation by the presence or absence of GLUT1 staining. The infantile or juvenile hemangioma, shown in **A,** often presents as multiple masses that usually involute and regress. Microscopically the lesions are sharply demarcated lobules composed of closely packed capillary-sized vessels that stain for the glucose transporter GLUT1. The other type, also known as hepatic vascular malformation, is usually a large single mass that often undergoes central infarction, does not regress, and may be associated with consumption coagulopathy. As shown in **B,** the area of infarct is surrounded by variably dilated thin-walled vessels with entrapped bile ducts and hepatocytes. The lesional vessels are negative for GLUT1. *(Courtesy of Dinesh Rakheja, MD, Children's Medical Center, Dallas, Tex.)*

FUTURE CHALLENGES IN TREATMENT OF PEDIATRIC LIVER TUMORS

Although cure rates for liver tumors, particularly hepatoblastoma, have increased over recent decades, many significant challenges remain. The rarity of these malignancies has contributed to the difficulty in the design and implementation of clinical trials, and each treatment hypothesis proposed may take many years to test. Agents of current interest for clinical application for hepatoblastoma include irinotecan and incorporation of sorafenib. Clinical trials for childhood HCC will likely parallel those for adult HCC and use multikinase inhibitors such as sorafenib in addition to chemotherapy.

Additional biologic markers for predicting prognosis and stratifying risk are needed. Although several molecular pathways have been identified in pediatric liver tumors, the integration of molecular characteristics in disease risk stratification and prognosis needs to be developed. In addition, more therapies specifically targeting relevant pathways are needed, with the additional goal of limiting toxicities.

The recently formed Children's Hepatic International Consortium will foster an exciting international collaboration in the analysis of risk factors and outcomes in hepatoblastoma, as well as accelerating new clinical approaches to the treatment of liver tumors in children.[190] This consortium has to date established a series of prognostic risk factors based on a compilation of international trials and will design future treatment strategies based on these classifications.

   The latest epidemiologic data on disease etiology and outcome by site and age, as compiled by the National Cancer Institute, is presented.

2. Weinberg A, Finegold M: Primary hepatic tumors of childhood. *Hum Pathol* 14:512–537, 1983.

   A classic article describing the spectrum of primary liver tumors in children in two large institutions, including discussion of etiologic factors and histologic characteristics of hepatoblastoma, HCC, and the less common liver tumors of childhood. An observation is made regarding the association of pure fetal histology and favorable outcome.

3. Lopez-Terrada D, Alaggio R, de Davila MT, et al: Towards an international pediatric liver tumor consensus classification: proceedings of the Los Angeles COG liver tumors symposium. *Mod Pathol* 27:472–491, 2014.

   A recent update of the classification of liver tumors in childhood from an international working group of pediatric pathologists. The classification described here will be used in upcoming international treatment protocols.

7. Perilongo G, Shafford E, Maibach R, et al: Risk-adapted treatment for childhood hepatoblastoma. Final report of the second study of the International Paediatric Oncology—SIOPEL 2. *Eur J Cancer* 40:411–421, 2004.

   This article describes treatment outcomes for standard risk (three sectors or less) and high risk (four or more sectors or metastatic). Standard-risk patients were given dose-intense cisplatin with a reported 97% subsequent resection rate and a 91% overall survival rate. High-risk patients were treated with dose-dense cisplatin alternating with carboplatin, with 67% subsequent resection rate and 53% overall survival rate.

32. Wang YX, Liu H: Adult hepatoblastoma: systemic review of the English literature. *Dig Surg* 29:323–330, 2012.

    Prior reports of hepatoblastoma in adults consisted primarily of single case reports. This represents a compilation of 36 prior reports of 40 cases, indicates a one-year survival rate is 29%, and underscores the importance of resection in obtaining cure.

33. Trobaugh-Lotrario AD, Chaiyachati BH, Meyers RL, et al: Outcomes for patients with congenital hepatoblastoma. *Pediatr Blood Cancer* 60:1817–1825, 2013.

    Congenital hepatoblastoma, once thought to have a poor outcome, was suggested to have a survival rate of 86% from this meta-analysis from U.S. and German series as well as a review of multiple published studies.

34. Prokurat A, Kluge P, Koscieza A, et al: Transitional liver cell tumors (TLCT) in older children and adolescents: a novel group of aggressive hepatic tumors expressing beta-catenin. *Med Pediatr Oncol* 39:510–518, 2002.

    This study observes that older children with hepatoblastoma may have more aggressive tumors that have characteristics of both HCC and hepatoblastoma—hence the term transitional liver cell tumor.

37. Katzenstein H, Krailo M, Malogolwkin M, et al: Hepatocellular carcinoma in children and adolescents: results from the Pediatric Oncology Group and the Children's Cancer Group intergroup study. *J Clin Oncol* 20:2789–2797, 2002.

    The results presented in this report from the Pediatric Intergroup Hepatoma Protocol INT-0098 treating childhood HCC according to chemotherapy protocols similar to those used for hepatoblastoma in North America demonstrate a dismal overall survival rate of 19% in HCC. Initial surgical resection was associated with a good prognosis.

39. Katzenstein H, Krailo M, Malogolowkin M, et al: Fibrolamellar hepatocellular carcinoma in children and adolescents. *Cancer* 97:2006–2012, 2003.

    This study reports no difference in 5-year survival rates for patients with fibrolamellar variant of HCC compared with the typical HCC, the although the median survival rate is longer. Unlike other liver tumors, the fibrolamellar HCCs occur equally in male and female patients.

56. Giardiello F, Offerhaus G, Krush A, et al: Risk of hepatoblastoma in familial adenomatous polyposis. *J Pediatr* 119:766–768, 1991.

    The data presented in this study from the Johns Hopkins Registry of 197 families with FAP covering 1220 person-years demonstrate that the relative risk of hepatoblastoma in children 0 to 4 years of age is a remarkable 846.

57. Hughes LJ, Michels VV: Risk of hepatoblastoma in familial adenomatous polyposis. *Am J Med Genet* 43:1023–1025, 1992.

58. Hirschman B, Pollock B, Tomlinson G: The spectrum of APC mutations in children with hepatoblastoma from familial adenomatous polyposis kindreds. *J Pediatr* 147:263–266, 2005.

    This study reports that in patients with hepatoblastoma who reported a family history of FAP, the spectrum of mutations found occurred throughout the gene, and there is no "hotspot" mutation in the APC gene for hepatoblastoma.

79. DeBaun M, Tucker M: Risk of cancer during the first four years of life in children from children from the Beckwith-Wiedemann Syndrome Registry. *J Pediatr* 132:398–400, 1998.

    National Cancer Institute data demonstrate the relative risk of hepatoblastoma in Beckwith-Wiedemann syndrome to be 2280, a higher relative risk than for any other embryonal tumor.

84. Clericuzio C, Chen E, NcNeil E, et al: Serum alpha-fetoprotein screening for hepatoblastoma in children with Beckwith-Wiedemann syndrome or isolated hemihyperplasia. *J Pediatr* 143:270–272, 2003.

    This study demonstrates in five patients that screening of children with Beckwith-Wiedemann syndrome or isolated hemihyperplasia with AFP as well as ultrasonography led to early detection in each case.

114. Tomlinson G, Douglass E, Pollock B, et al: Cytogenetic analysis of a large series of hepatoblastoma: numerical aberrations with recurring translocations involving 1q12-21. *Genes Chromosomes Cancer* 44:177–184, 2005.

     Cytogenetic analyses in a large series demonstrate that numeric aberrations of whole chromosomes are the most common feature of hepatoblastoma. In addition, a family of unbalanced *translocations involving chromosomal breakpoints at proximal chromosome 1q is described.*

121. Knisely A, Strautnieks S, Meier Y, et al: Hepatocellular carcinoma in ten children under five years of age with bile salt export pump deficiency. *Hepatology* 44:478–486, 2006.

  This study shows an interesting association of HCC and bile salt export pump deficiency and associated germline mutation.

151. Tanimura M, Matsui I, Abe J, et al: Increased risk of hepatoblastoma among immature children with a lower birth weight. *Cancer Res* 1998:3032–3035, 1998.

  Data from the Japanese Children's Cancer Registry show an increase in hepatoblastoma in low-birth-weight children born after 1988, when survival rates among low-birth-weight children began to increase. The relative risks of hepatoblastoma in low-birth-weight infants compared with infants weighing more than 2500 g vary inversely with birth weight, with the highest relative risk calculated as 15.64 for infants born at less than 2500 g.

158. Musselman JR, Georgieff MK, Ross JA, et al: Maternal pregnancy events and exposures and risk of hepatoblastoma: a Children's Oncology Group (COG) study. *Cancer Epidemiol* 37:318–320, 2013.

  A Children's Oncology Group study of maternal events and hepatoblastoma risks found little evidence of illness or medication during pregnancy affecting risk of hepatoblastoma.

160. Williams CL, Bunch KJ, Stiller CA, et al: Cancer risk among children born after assisted conception. *N Engl J Med* 369:1819–1827, 2013.

  A large cohort study from the United Kingdom demonstrated no definitive over all risk of childhood cancer after assisted conception, although a very small increased risk of hepatoblastoma was reported.

166. Chang M, Chen C, Lai M, et al: Hepatitis B vaccination in Taiwan and the incidence of hepatocellular carcinoma in children. Taiwan Childhood Hepatoma Study Group. *N Engl J Med* 336:1855–1859, 1997.

  A demonstration that universal hepatitis B vaccination resulted in a decline in the incidence of childhood hepatocellular carcinoma in Taiwan.

CHAPTER 59

Rhabdomyosarcoma

Richard B. Womer, Frederic G. Barr, and Corrine M. Linardic

CHAPTER OUTLINE

PATHOLOGIC CLASSIFICATION OF RHABDOMYOSARCOMA
RHABDOMYOSARCOMA IN CANCER PREDISPOSITION SYNDROMES
GENETICS OF SPORADIC RHABDOMYOSARCOMA
Gene Fusions Generated by Chromosomal Rearrangements
Chromosome Copy Number Changes
Amplification of Specific Chromosomal Regions
Allelic Loss Events
Oncogene and Tumor Suppressor Gene Mutations in Rhabdomyosarcoma
Hypermethylation as an Alternative Mechanism of Gene Inactivation in Rhabdomyosarcoma
APPLICATIONS OF MOLECULAR GENETIC APPROACHES TO DIAGNOSIS AND PROGNOSIS
Detection of Recurrent Gene Fusions
Pathologic and Clinical Differences between Fusion Subtypes
Gene Expression Profiling with Microarrays
Detection of Rhabdomyosarcoma in Sites Other Than Primary Tumor
MOLECULAR AND CELLULAR BIOLOGY OF RHABDOMYOSARCOMA
Myogenic Pathways in the Tumorigenesis of Rhabdomyosarcoma
MicroRNAs
Epigenetic Regulation
Role of Insulin-like Growth Factors in Rhabdomyosarcoma
Modulation of Growth and Apoptotic Pathways by Fusion Oncoproteins
Metastatic Pathways in Rhabdomyosarcoma
PRECLINICAL INVESTIGATION OF EMERGING DRUG TARGETS FOR RHABDOMYOSARCOMA
Preclinical Models to Study Rhabdomyosarcoma Tumorigenesis
Inhibitors of Receptor Tyrosine Kinases
Inhibitors of Intracellular Signaling Pathways
Inhibitors of Developmental Pathways
Inhibitors of Other Cellular Processes That Support Rhabdomyosarcoma Tumorigenesis
Immunotherapy for Rhabdomyosarcoma
CLINICAL RESEARCH ON RHABDOMYOSARCOMA
INCIDENCE AND EPIDEMIOLOGY
CLINICAL PRESENTATION AND EVALUATION
RISK GROUP CLASSIFICATION
Histology and Fusion Status
Site
Age
Invasiveness and Size (Tumor Stage)
Clinical Group
Lymph Node Involvement
Metastases at Diagnosis
Interactions
TREATMENT
Chemotherapy
Primary Tumor Treatment
Special Situations
FOLLOW-UP AFTER TREATMENT
Surveillance and Patterns of Recurrence
Late Effects
FUTURE DIRECTIONS

PATHOLOGIC CLASSIFICATION OF RHABDOMYOSARCOMA

The term *rhabdomyosarcoma* (RMS) comprises a heterogeneous family of soft tissue cancers that are related in poorly understood ways to the skeletal muscle lineage. Some of these tumors occur in the vicinity of skeletal muscle, but others occur in areas without obvious skeletal muscle; thus these cancers cannot be defined solely as tumors of skeletal muscle. Instead, this family is derived from unknown mesenchymal precursors and is characterized by a shared program of skeletal myogenesis. Despite this shared program, some precursors may intrinsically undergo myogenesis whereas others may have developed this ability aberrantly.

Histopathologic classification has evolved over time, but two principal histopathologic subtypes have been recognized consistently in children: alveolar RMS (ARMS) and embryonal RMS (ERMS).[1] The criteria for these categories were refined over time as these subtypes were associated with clinically distinct phenotypes. As described in detail later, ARMS more often occurs in the extremities and axial musculature in older children and is associated with a less favorable prognosis whereas ERMS tends to occur in the head, neck, and genitourinary tract of younger patients and is associated with a favorable prognosis. ARMS and ERMS account for 20% to 30% and 70% to 80% of RMS cases, respectively.

The diagnosis of RMS is often difficult because of the paucity of features of striated muscle differentiation. A variety of pediatric solid tumors, including RMS, neuroblastoma, Ewing sarcoma, and non-Hodgkin lymphoma, can present as collections of poorly differentiated cells (small round blue cell tumors). To detect more subtle evidence of myogenic differentiation, immunohistochemical reagents are used to identify muscle-specific proteins, such as MYOD, myogenin, desmin, myoglobin, and skeletal muscle-specific actin.[2] In addition, the detection of myofilaments by electron microscopy provides further evidence of the myogenic phenotype.

In ARMS, the tumor cells are small blue round cells with only small amounts of cytoplasm (Fig. 59-1, *A*).[3] The prominent round nuclei generally have monotonous, coarse chromatin, and central nucleoli are often present. These tumor cells form highly cellular aggregates separated by fibrovascular septa. Within these aggregates, discohesive areas tend to form, resulting in spaces or clefts lined by rhabdomyoblasts. ARMS was named for these open spaces, which have an appearance reminiscent of pulmonary alveoli. In addition to these features, the tumor cells tend to align along septa in a "picket-fence" pattern and tumor giant cells are often present. In a subset of cases there is a paucity of fibrovascular stroma, no evidence of spaces, and the predominance of a highly cellular small round cell population with cytologic features similar to the classic alveolar pattern; such cases are referred to as the solid variant of ARMS.

ERMS is so named because of its histologic similarity to developing skeletal muscle. The tumor cells show varying degrees of differentiation along the myogenic spectrum, from small primitive round cells to larger oblong cells with eccentric oval nuclei and varying amounts of eosinophilic cytoplasm (see Fig. 59-1, *B*).[3] ERMS nuclei are often notable for a relatively bland chromatin pattern. These differentiated cells can elongate to assume a straplike appearance and occasionally show cross-striations and multinucleation. In addition to the characteristic cytology, ERMS tumors classically have variable cellularity, in which areas of hypercellularity alternate with areas of hypocellularity in a loose myxoid stroma.

Within the ERMS category, there are several histologic variants. In sclerosing RMS, there is abundant desmoplasia and the tendency to form microalveolar tumor cell nests within the desmoplastic areas[4]; in some cases, this microalveolar appearance has been mistaken for ARMS. In a second variant, there are dense clusters of ERMS cells that can be confused with the solid variant of ARMS[5]; this dense ERMS variant can be distinguished based on cytologic features and other special studies. Finally, two variants of ERMS have been associated with

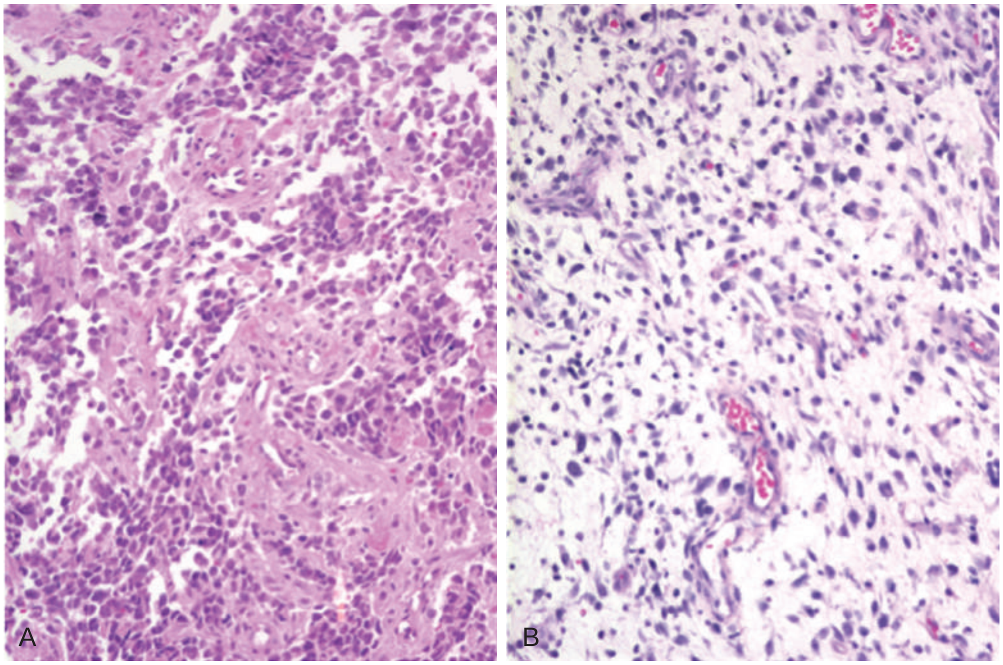

Figure 59-1 Histopathology of RMS subtypes. **A,** Alveolar rhabdomyosarcoma (hematoxylin-eosin, original magnification ×100). **B,** Embryonal rhabdomyosarcoma (hematoxylin-eosin, original magnification ×100). *(Courtesy Dr. Bruce Pawel, Children's Hospital of Philadelphia.)*

an improved prognosis.[3] Botryoid RMS typically occurs in the lumen of a hollow viscus, such as the urinary bladder, vagina, or extrahepatic bile ducts, and grossly has multiple polypoid nodules. At the microscopic level, this tumor typically has a dense cambium layer of tumor cells under an intact epithelial surface. Spindle-cell RMS has dense bundles or whorls of spindle-shaped cells that resemble smooth muscle. In children, these lesions commonly occur in the paratesticular region, but in adults, in whom the prognosis is worse, these lesions tend to occur in the head and neck and are often associated with a sclerosing pattern. In both of these latter two variants, the tumors cells can show marked rhabdomyoblastic differentiation.

Another small subset of RMS cases demonstrates discrete areas with ERMS-like histology and separate discrete areas with ARMS-like histology.[5] The ERMS-like and ARMS-like areas can have any one of the various histologic patterns described earlier. Although these cases were previously diagnosed as ARMS or ERMS based on prevailing histopathologic criteria, these cases are currently classified as mixed RMS.

A final RMS subset shows features similar to anaplastic Wilms tumors.[6] Although the anaplasia can be seen in both ARMS and ERMS, it is more prevalent in the latter. Anaplastic RMS tumors have large, lobated hyperchromatic nuclei and atypical mitoses. In some cases anaplastic cells are scattered in small patches (focal anaplasia), whereas other cases have larger clusters or sheets of anaplastic cells (diffuse anaplasia).

RHABDOMYOSARCOMA IN CANCER PREDISPOSITION SYNDROMES

The majority of RMS cases arise as sporadic nonheritable tumors, but a small fraction of cases are associated with heritable genetic syndromes (Table 59-1). In some cases the proband with RMS inherited a mutant gene as part

TABLE 59-1 Familial Cancer Predisposition Syndromes Associated with Rhabdomyosarcoma

Cancer Syndrome	Locus	Gene	Nonneoplastic Findings	Characteristic Tumors	Frequency of RMS
Costello syndrome	11p15.5	*HRAS*	Facial anomalies, cardiac hypertrophy, cognitive defects, developmental delay	*Benign:* skin papillomas *Malignant:* RMS, neuroblastoma, bladder cancer	7%
Li-Fraumeni syndrome	17p13.1 22q12.1	*TP53* *CHEK2*	None	Sarcoma, breast cancer, brain tumor, adrenocortical cancer, leukemia	6%
Hereditary retinoblastoma	13q14	*RB1*	None	Retinoblastoma, osteosarcoma	2%
Neurofibromatosis type 1	17q11.2	*NF1*	Café au lait spots, skinfold freckling, Lisch nodules, cognitive deficits	*Benign:* neurofibroma *Malignant:* MPNST, AML	1%
Constitutional mismatch-repair-deficiency syndrome	7p22.2 and others	*PMS2, MLH1, MSH2, MSH6*	Café au lait spots	hematologic cancers, brain tumors, colorectal cancer	1%
Beckwith-Wiedemann syndrome	11p15.5	Unknown	Macrosomia, macroglossia, hemihyperplasia, visceromegaly	Wilms tumor, hepatoblastoma	<1%
Nevoid basal cell carcinoma syndrome	9q22	*PTCH*	Macrocephaly, skin cysts, palmar and plantar pits, rib anomalies	Basal cell carcinoma, medulloblastoma	<1%
Rubinstein-Taybi syndrome	16p13.3	*CREBBP*	Mental retardation, facial anomalies, and broad thumbs	Leukemia, brain tumors	<1%
Noonan syndrome	12q24 and others	*PTPN11, SOS1, RAF1,* and others	short stature, facial anomalies, congenital heart defects	Neuroblastoma, ALL, glioma, RMS	<1%
DICER1 syndrome (formerly PPB family tumor and dysplasia syndrome)	14q32	*DICER1*	None	PPB, cystic nephroma	Unknown

ALL, Acute lymphoblastic leukemia; *AML,* acute myelogenous leukemia; *MPNST,* malignant peripheral nerve sheath tumor; *PPB,* pleuropulmonary-blastoma; *RMS,* rhabdomyosarcoma.

of an established familial syndrome, and in other cases a new germline mutation occurred in one germ cell that ultimately produced the proband. The penetrance of RMS in individuals with new or inherited germline mutations varies from as high as approximately 7% in Costello syndrome to 0.1% to 1% in other syndromes. Although there are rare cases of RMS found in association with other syndromes, the determination that such syndromes increase predisposition to RMS is limited by the overall low frequency of these syndromes. In a similar way, the small contribution of known RMS susceptibility syndromes to the overall incidence of RMS is related to the low incidence of these syndromes in the general population. Neurofibromatosis type 1 has the highest prevalence, occurring in approximately 1 in 3500 individuals and accounting for about 1% of all RMS cases.[7,8] Although *TP53* germline mutations occur less frequently (~1 in 20,000 individuals), there is a higher prevalence of RMS in these mutation carriers; thus this susceptibility syndrome has been reported to occur in up to 10% all RMS cases.[9]

Among the syndromes predisposing to RMS, three syndromes (termed *RASopathies*) are caused by alterations of the RAS signaling pathway. Costello syndrome is caused by mutations in *HRAS* codons 12 or 13.[10] These same mutations commonly occur in many types of sporadic tumors, have transforming activity in cell culture, and thus are gain-of-function alleles. Similarly, Noonan syndrome is caused by activating mutations of one of several oncogenes encoding downstream RAS pathway components with growth stimulatory function.[11] In contrast, neurofibromatosis type 1 is caused by inactivating mutations of the *NF1* tumor suppressor gene, which encodes neurofibromin, a guanosine triphosphatase–activating protein that negatively regulates RAS signaling.[12] The presence of a common affected signaling pathway is also indicated by the significant overlap in nonneoplastic phenotype in both Costello and Noonan syndromes. In contrast, neurofibromatosis type 1 is associated with different nonneoplastic phenotypic features. Analysis of these heritable syndromes has thus shown that activation of RAS signaling by one of several genetic changes leads to a low and variable frequency of RMS susceptibility.

The RMS tumors associated with these hereditary predisposition syndromes display a number of notable properties. In many of these syndromes, the RMS tumors occur at a younger age than sporadic RMS tumors, which is in accord with the two-hit tumor susceptibility gene model.[13] Of note, RMS cases in hereditary retinoblastoma occur at a later age but are associated with radiation treatment of the primary retinoblastoma, thus suggesting the need for a postnatal DNA damage event for RMS in this setting.[14] From a pathology perspective, most of these syndromic RMS tumors are diagnosed as ERMS, the subtype that is not associated with the *PAX3-FOXO1* and *PAX7-FOXO1* gene fusions (described later).[11] In the few cases in which tumors are described as ARMS, such as in hereditary retinoblastoma or Beckwith-Wiedemann syndrome, molecular testing reveals that these RMS tumors are fusion negative.[15,16]

GENETICS OF SPORADIC RHABDOMYOSARCOMA

Gene Fusions Generated by Chromosomal Rearrangements

Cytogenetic studies established that nonrandom chromosomal translocations distinguish most ARMS tumors from ERMS and other pediatric solid tumors (Fig. 59-2). A translocation involving chromosome 2 and 13, t(2;13)(q35;q14), was found in 56% of 99 published ARMS cases, and a variant translocation involving chromosome 1 and 13, t(1;13)(p36;q14), was identified in 6% of cases (http://cgap.nci.nih.gov/Chromosomes/Mitelman). This latter fraction is probably an underestimate because the 1;13 translocation is usually followed by an amplification event (see later). In contrast to ARMS, the 2;13 and 1;13 translocations were found in 3% and 0% of 77 published ERMS cases, respectively. Such rare translocation-positive ERMS cases may represent tumors with mixed histology or misdiagnosed ARMS tumors.

At the molecular level, the 2;13 and 1;13 translocations break and rejoin portions of transcription factor–encoding genes to generate fusion genes expressed as fusion transcripts (see Fig. 59-2). The rearranged genes on chromosomes 2 and 1 are *PAX3* and *PAX7*, which encode related members of the paired box family.[17,18] The chromosome 13 locus in these translocations is *FOXO1 (FKHR)*, which encodes a member of the forkhead family.[19] Although two reciprocal fusion genes, *PAX3-FOXO1* and *FOXO1-PAX3* (or *PAX7-FOXO1* and *FOXO1-PAX7*), are formed by these translocations, the higher and more consistent expression of *PAX3-FOXO1* or *PAX7-FOXO1* supports the premise that the *PAX3-FOXO1* or *PAX7-FOXO1* products are involved in ARMS pathogenesis.

The *PAX3-FOXO1* and *PAX7-FOXO1* fusion transcripts are translated into novel chimeric transcription factors (see Fig. 59-2).[18,19] The wild-type *PAX3, PAX7,* and *FOXO1* genes encode transcription factors organized with an amino-terminal (N-terminal) DNA-binding domain and a carboxy-terminal (C-terminal) transcriptional activation domain. The translocations break within *PAX3* or *PAX7* intron 7 and maintain an intact DNA-binding domain but separate it from an essential part of the transactivation domain. In addition, the translocations break within *FOXO1* intron 1 and disrupt the DNA-binding domain but maintain an intact transactivation domain. In the chimeric transcripts, the 5′ *PAX3* (or 5′ *PAX7*) and 3′ *FOXO1* coding sequences are fused in-frame to generate a 2508- or 2484-nucleotide open reading frame encoding an 836- or 828-amino acid fusion protein, respectively. These fusion proteins contain the first seven exons of *PAX3* or *PAX7,* including an intact DNA-binding domain, and the last two exons of *FOXO1,* including an intact transactivation domain. A functional fusion protein cannot be created by other combination of *PAX3* and *FOXO1* exons because of incompatible reading frames or loss of functional domains. These rearrangements of *PAX3* or *PAX7* intron 7 and *FOXO1* intron 1 thus appear to be selected because of functional constraints related to genomic organization of *PAX3, PAX7,* and *FOXO1.*

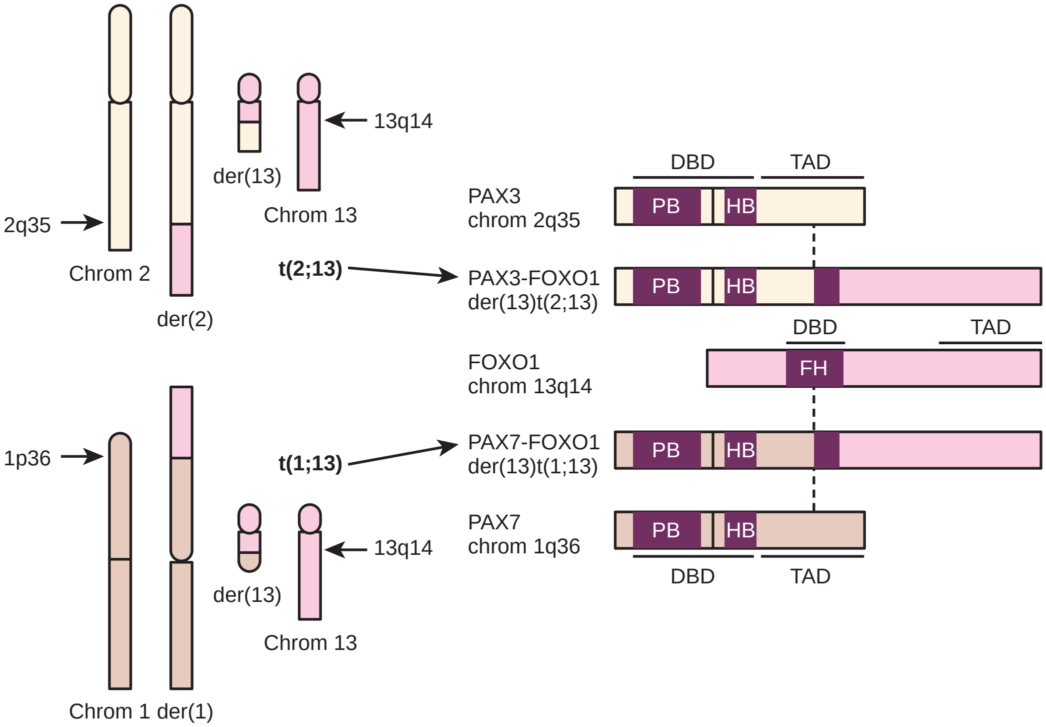

Figure 59-2 Diagrams of 2;13 and 1;13 chromosomal translocations and associated fusion products. A schematic representation of the normal and derivative chromosomes associated with t(2;13) and t(1;13) is shown on the left. The translocation breakpoints are indicated by *short horizontal arrows* with the location of involved chromosomal region. The wild-type and fusion products associated with 2;13 and 1;13 translocations are shown on the right. The paired box (PB), octapeptide, homeobox (HB), and forkhead (FH) domains are indicated as *dark purple boxes,* and transcriptional domains (DBD, DNA binding domain; TAD, transcriptional activation domain) are shown as *solid bars.* The *vertical dashed line* indicates the translocation fusion point.

There are changes in both function and expression caused by the fusion events in ARMS. The chimeric transcription factors activate transcription from PAX3/PAX7-binding sites but are much more potent as transcriptional activators than the wild-type PAX3 and PAX7 proteins.[20,21] This difference in transcriptional activity appears to be caused by a decreased sensitivity of the FOXO1 activation domain to the inhibitory effects of N-terminal PAX3 (or PAX7) domains, when compared with the effect of these N-terminal domains on the PAX3 (or PAX7) activation domain. The fusion proteins may also have a relaxed capability to bind and activate target genes owing to increased structural flexibility in the N-terminal DNA-binding domain.[22] In addition to changes in transcriptional function, the PAX3-FOXO1 or PAX7-FOXO1 fusion products are expressed in ARMS tumors at higher levels compared with the corresponding wild-type PAX3 or PAX7 products.[23] The gene-specific mechanisms for this enhanced fusion product expression are described later. Therefore these chromosomal changes result in high levels of chimeric transcription factors that inappropriately activate transcription of genes with PAX3/PAX7 DNA-binding sites. These biologic effects contribute to tumorigenesis by modulating myogenic differentiation, altering growth and apoptotic pathways, and stimulating motility and other metastatic pathways.

Several methodologies, including reverse-transcriptase polymerase chain reaction (RT-PCR) assay and fluorescent in situ hybridization (FISH), were applied to detect the *PAX3-FOXO1* and *PAX7-FOXO1* fusions in clinical material.[24-27] A single large study of RMS cases from the Intergroup Rhabdomyosarcoma Study (IRS) IV protocol showed that all 93 cases of RMS or undifferentiated sarcoma with a diagnosis other than ARMS were fusion negative, whereas 77% of the 78 ARMS cases were fusion positive.[28] Of these ARMS cases, 55% expressed *PAX3-FOXO1,* 22% expressed *PAX7-FOXO1,* and 23% were fusion negative.[28] These findings were confirmed by several other large cooperative group studies. In other studies of mixed RMS, most but not all cases were fusion negative.[27,29] Furthermore, when areas with ARMS-like and ERMS-like histology were individually examined by FISH, there was concordance for fusion status among the regions in a single tumor.

These molecular pathology studies establish that there is a significant subset (~20%) of ARMS cases that do not express either the *PAX3-FOXO1* or *PAX7-FOXO1* fusion. The IRS IV protocol and subsequent cooperative group studies used centralized pathology review and uniform tissue banking, and thus these fusion-negative results cannot be explained by inaccurate histopathologic diagnosis or suboptimal tissue samples. Subsequent analysis of these fusion-negative cases revealed that a small subset have variant fusions of *PAX3, PAX7,* or *FOXO1* with other genes, including fusion of *PAX3* with the *FOXO1*-related locus *FOXO4 (AFX1)* and fusion of *PAX3* with *NCOA1* or *NCOA2,* which encode two similar transcription factors unrelated to the forkhead family.[30,31] However, these variant fusions are uncommon; most fusion-negative ARMS cases do not have any rearrangements of *PAX3, PAX7,* or *FOXO1* and thus appear to represent true fusion-negative cases with respect to these loci.

Although genetic studies have not revealed any chromosome rearrangements that occur in most ERMS cases, gene fusions have been identified in a small number of ERMS cases. In particular, rearrangements of the *NCOA2* gene in the 8q11-13 chromosomal region were detected in four ERMS tumors.[31,32] The pathologic subtype in three of the four cases was a spindle cell variant of ERMS. Furthermore, all four cases occurred in infants younger than 1 year of age and thus are characterized as congenital/infantile RMS. Further analysis of three cases demonstrated fusions to different partners in each case—*PAX3* (2q35), *SRF* (8q11), and *TEAD1* (11p15). Finally, there is a report of an unrelated fusion, *EWSR1-DUX4,* in an ERMS in a 19-year-old patient.[33]

Chromosome Copy Number Changes

Various studies, including classic cytogenetics (http://cgap.nci.nih.gov/Chromosomes/Mitelman), chromosome-based comparative genomic hybridization (CGH), and DNA-based microarrays established that a second set of differences between the RMS histopathologic subtypes is at the level of whole chromosome gains and losses.[34,35-37] ERMS tumors have multiple numerical changes of whole chromosomes. The most frequent chromosome change in ERMS involves gains of chromosome 8. This change is characterized by polysomy, or multiple copies, of chromosome 8 and occurs in 50% to 90% of ERMS tumors but only 10% to 20% of ARMS tumors. This chromosome gain results in elevated expression of genes along chromosome 8 and cannot be localized to any specific chromosomal region. Additional common gains in ERMS involve chromosomes 2, 7, 11, 12, 13, and 20. In contrast to chromosome 8 gains, each of these latter changes is often a low-level gain, most likely a trisomy, and occurs in 20% to 50% of ERMS cases. Several of these gains, such as chromosome 2, 11, and 13, occur at significantly lower frequencies (2- to 10-fold) in ARMS tumors. Whole chromosome losses in ERMS commonly involve chromosomes 6, 9, 10, 14, 15, and 16 and occur in 15% to 25% of ERMS tumors. A study of intermediate-risk ERMS reports higher frequencies of these chromosome losses, suggesting that these events may vary among RMS risk groups.[35] There are also quantitative differences in chromosome losses between ERMS and ARMS, but these differences are not as striking as the differences involving gains.

Although the chromosome gains and losses are not prevalent in the ARMS cases as a group, the fusion-negative ARMS subset has a pattern of gains and losses that is much more similar to ERMS than to the fusion-positive ARMS subset.[37] The most striking finding involves chromosome 8; these events occur in more than 50% of fusion-negative ARMS tumors but not in fusion-positive ARMS tumors. As a second example, chromosome 11 gains occur in 30% of fusion-negative ARMS tumors but only 10% of fusion-positive ARMS tumors.

TABLE 59-2 Frequently Amplified Chromosomal Regions in Rhabdomyosarcoma

		FREQUENCY		
Chromosome Region	**Genes Involved**	*PAX3-FOXO1*	*PAX7-FOXO1*	Fusion-negative
1p36	*PAX7*	0%	>90%	0%
2p24	*MYCN*	20%	20%	0-6%
12q13-14	*CDK4* and others	24	<5%	<5%
13q14	*FOXO1*	<10%	>90%	0%
13q31	*MIR17HG*	<10%	70%	<10%

Amplification of Specific Chromosomal Regions

CGH and DNA-based microarray studies revealed that ARMS has significantly more genomic amplification events than ERMS. In CGH studies, one or more amplification events were detected in 47 of 84 ARMS cases (56%) compared with 7 of 43 ERMS cases (16%).[34,38,39] The most common amplicons in ARMS tumors were derived from chromosomal regions 1p36, 2p24, 12q13-q14, 13q14, and 13q31 (Table 59-2).[38,40-42] The pattern of changes in the fusion-negative ARMS subset was again more similar to the pattern in ERMS than that in fusion-positive ARMS.[37] This difference is exemplified by the finding of 12q13-q14 amplification in 24% of fusion-positive ARMS, 4% of fusion-negative ARMS, and 0% of ERMS. In addition to differences between fusion-positive and fusion-negative tumors, many of these high-frequency amplicons have a marked preference for either the *PAX3-FOXO1*– or *PAX7-FOXO1*–positive subset .

The amplification events at 1p36 and 13q14 generally occur in the same cases and are indicative of *PAX7-FOXO1* amplification (see Table 59-2).[41] In particular, *PAX7-FOXO1* is amplified in more than 90% of *PAX7-FOXO1*–positive cases whereas *PAX3-FOXO1* is amplified in less than 10% of *PAX3-FOXO1*–positive cases. As a further difference, there is a higher number of cells containing the amplicon in amplified *PAX7-FOXO1*–positive cases than in amplified *PAX3-FOXO1*–positive cases. At the expression level, the fusion transcript is expressed at higher levels in *PAX7-FOXO1*–positive cases than in *PAX3-FOXO1*–positive cases. Despite these differences, both fusion products are expressed in ARMS tumors at higher levels than the corresponding wild-type *PAX3* or *PAX7* products.[23] This high expression is postulated to generate a fusion product level above a critical threshold for oncogenic activity. Although there is a common feature of fusion overexpression in fusion-positive ARMS, the mechanism of overexpression differs between the two subtypes. In *PAX7-FOXO1*–positive tumors, the fusion is generally overexpressed because of genomic amplification, a copy number–dependent mechanism. In contrast, *PAX3-FOXO1* is generally overexpressed by a copy number–independent increase in transcriptional rate.

For amplification of the 2p24 chromosomal region, the minimal amplified region contains the *MYCN* protooncogene (see Table 59-2).[40] This genomic region corresponds to the same region that is frequently amplified in neuroblastoma. In ARMS there is a comparable incidence of 2p24 amplification (20%) in *PAX3-FOXO1*– and *PAX7-FOXO1*–positive tumors. In contrast, this amplification occurs very infrequently in ERMS and fusion-negative ARMS tumors (0% to 6% of cases).[37] In addition to amplification, low copy number gains, which may be explained in part by whole chromosome 2 gains, were found in 50% to 60% of ARMS and ERMS cases.[43] In fusion-positive tumors, 2p24 amplification generally results in high expression of the *MYCN* transcript and an increase in MYCN protein expression. The lower-level gains may also be associated with moderate increases in *MYCN* expression.

Amplification of the 12q13-q14 chromosomal region was found in numerous cancers, including bone and soft tissue sarcomas (e.g., osteosarcoma and liposarcoma), brain tumors (mostly glioblastoma), and carcinomas (including breast cancer).[44] In ARMS, the minimal amplified region was localized to a 0.5-Mb region containing more than 20 genes, including CDK4, which encodes a cell cycle regulatory protein (see Table 59-2).[40] The 12q13-q14 region is amplified preferentially in *PAX3-FOXO1*–positive cases; there is a 24% and 4% frequency of 12q13-q14 amplification in *PAX3-FOXO1*– and *PAX7-FOXO1*–positive cases, respectively. This amplification also occurs at a low frequency in fusion-negative RMS tumors. In fusion-positive RMS tumors, 12q13-q14 amplification is associated with increased expression of multiple (but not all) genes in the minimal amplified region. Of note, the nearby 12q15 region (containing *MDM2*) is independently amplified at a low frequency in both fusion-positive and fusion-negative RMS tumors.[40,45-47]

The 13q31 amplification event was localized to a 150-kb region surrounding the *MIR17HG* gene (see Table 59-2).[42] This gene contains the miR-17-92 cluster, and the transcript expressed from the *MIR17HG* gene is processed to six microRNAs (miRs). This 13q31 region is also amplified in diffuse large B-cell lymphoma and small cell lung carcinoma.[48] In RMS, this region is preferentially amplified in *PAX7-FOXO1*–positive cases; this amplicon is present in 70% of *PAX7-FOXO1*–positive cases and less than 10% of *PAX3-FOXO1*–positive RMS and fusion-negative RMS cases. In RMS tumors with 13q31 amplification, five of the six microRNAs in the cluster (miR-17, miR-19a, miR-19b, miR-20a, and miR-92a) are expressed at high levels. Transcripts from a number of tumor suppressor genes are targets of these microRNAs, and thus these microRNAs are postulated to be oncogenic by decreasing tumor suppressor expression.

Allelic Loss Events

RMS studies using polymorphic markers to distinguish between the two alleles at a locus reveal that allelic loss (or conversion to homozygosity) occurs commonly in ERMS tumors.[49] With the use of DNA-based arrays with polymorphic markers, the genome-wide incidence of allelic loss (termed *fractional allelic loss*) was twofold higher in ERMS compared with ARMS tumors.[50] Furthermore, the fusion-negative ARMS subset demonstrated a fractional allelic loss similar to that of ERMS tumors that was more than twofold higher than that of fusion-positive ARMS tumors.

In ERMS, chromosome 11 is most commonly affected by allelic loss, and the smallest region of consistent allelic loss is 11p15.5 (Fig. 59-3).[51] This 11p15.5 allelic loss is also detected in a small subset (24%) of fusion-positive ARMS tumors but is much more common (77%) in ERMS and fusion-negative ARMS tumors.[50,52] The probable presence of a tumor suppressor gene in this region, which is inactivated in RMS, is supported by several pieces of evidence. First, the gene or genes responsible for Beckwith-Wiedemann syndrome (which predisposes to several cancers, including RMS) were localized to this chromosomal region.[53] Second, transfer of wild-type copies of chromosome 11 or fragments containing the 11p15 region suppresses growth of ERMS cells.[54,55]

Determination of the parent of origin of the two alleles from the 11p15.5 region revealed that ERMS tumors preferentially maintain the paternal allele and lose the maternal allele (see Fig. 59-3).[56] This preference suggests the action of genomic imprinting, a normal epigenetic developmental process that selectively inactivates expression of alleles in a gamete-of-origin–dependent process. Several genes in the human 11p15 chromosomal region and the corresponding mouse region show imprinting.[53] For example, *IGF2*, encoding an embryonic growth factor, is preferentially expressed from the paternal allele, whereas *CDKN1C*, which encodes a cyclin-dependent kinase inhibitor (p57/KIP2) that negatively regulates cell-cycle progression, is preferentially expressed from the maternal allele. Two additional genes with preferential maternal expression and tumor suppressor function derive from opposite strands of the *H19* locus, which produces the nontranslated H19 RNA, and the HOTS nucleolar protein.[57] These combined studies of allelic loss in the 11p15.5 region suggest that ERMS tumorigenesis frequently involves inactivation of an imprinted tumor suppressor by allelic loss of the active maternal allele and retention of the inactive paternal allele.

Oncogene and Tumor Suppressor Gene Mutations in Rhabdomyosarcoma

The earlier-described studies of RMS patients with cancer predisposition syndromes revealed genes that are mutated and corresponding pathways that are altered in the pathogenesis of rare RMS cases. In particular, RMS cases occurred in syndromes in which the RAS pathway was activated whereas other cases occurred in syndromes in which the RB1 or TP53 signaling pathway was inactivated. The corresponding pathways thus are strong candidates for alterations in sporadic tumors, either by mutating the same genes that are altered in the predisposition syndromes or mutating other genes in these pathways.

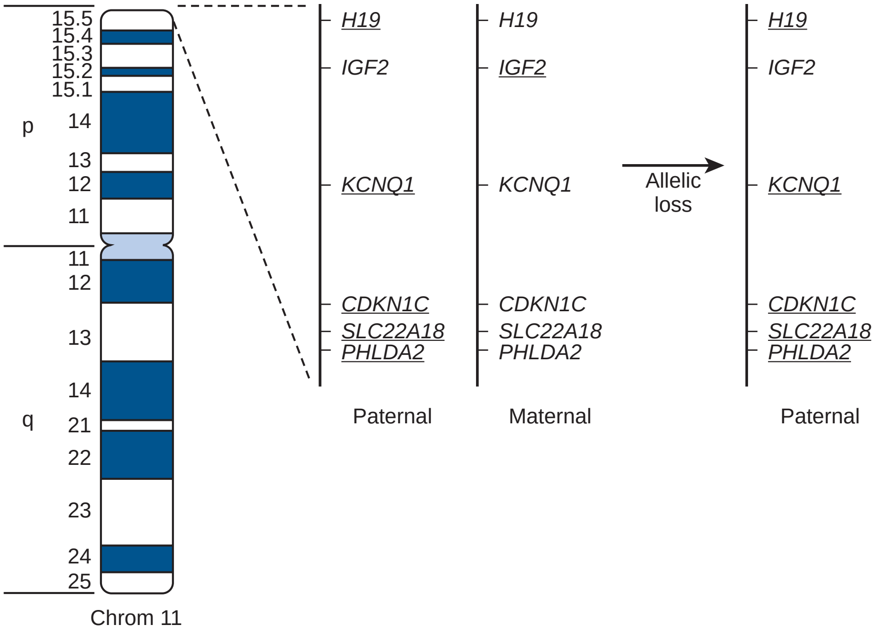

Figure 59-3 Allelic loss of imprinted region at 11p15.5 in RMS. In the 11p15.5 chromosomal region, there is parent-of-origin-specific expression (imprinting) of multiple genes, such that *underlining* indicates an expressed allele and lack of underlining indicates an unexpressed allele. In many cases of ERMS, a few cases of ARMS, and other tumors, the maternal alleles in the 11p15.5 region (and variable amounts of contiguous regions) are lost by one of a variety of genomic mechanisms in a process termed *allelic loss, loss of heterozygosity,* or *conversion to homozygosity.*

Several studies suggest that small mutations are more common in ERMS than ARMS. In a recent next-generation sequencing (NGS) study of 147 RMS cases (53 fusion-positive and 94 fusion-negative), the mean rate of verified nonsynonymous mutations was fourfold higher in fusion-negative tumors (17.8 mutations/tumor) compared with fusion-positive tumors (6.4 mutations/tumor).[58] Recurrent deleterious point mutations involving known genes were found in more than 50% of fusion-negative RMS cases compared with less than 5% of fusion-positive cases. Of note, only two recurrent point mutations (*PIK3CA* and *BCOR*) were found in the 48 fusion-positive ARMS cases whereas three recurrent point mutations were found in 11 fusion-negative ARMS cases. These overall findings in this NGS study were very similar to a second smaller NGS study[59] as well as a directed mutation study.[60] In this latter directed mutation study of 31 genes, mutations were detected in 14 of 57 (25%) ERMS cases compared with 1 of 21 (5%) ARMS cases.[60] Except for one ERMS case with two mutations, the other 13 ERMS cases had only one mutation per case from this panel of 31 genes. An insufficient number of cases was examined to comment on mutation frequency in the fusion-negative ARMS subset.

The RAS pathway is frequently activated in sporadic ERMS tumors by mutations in one of several genes (Table 59-3). In recent studies analyzing 147 ERMS cases, *RAS* family genes were mutated in 20% of ERMS cases.[35,60-63] More than half of these *RAS* family mutations (19/31, 61%) occurred in the *NRAS* gene and the majority (15/19, 79%) of these *NRAS* mutations involved codon 61. In contrast, only one *RAS* family gene mutation (in *KRAS*) was detected in 41 cases of ARMS (2%). Of various other RAS pathway components, *PTPN11* and *BRAF* mutations were found in 3% and 1% of ERMS cases but not in any ARMS cases.[60-65] In 1 of 12 ERMS cases (8%), a mutation was also found in the *SPRY1* gene, which encodes a modulator of RAS signaling.[63] Finally, homozygous deletions involving the *NF1* locus were found in 15% of ERMS cases.[35] The *RAS*, *PTPN11*, and *BRAF* point mutations as well as the *NF1* deletions are mutually exclusive, consistent with the premise that these changes activate the same pathway. Therefore, one of several components in the RAS pathway can be altered to activate this pathway in more than 40% of sporadic ERMS cases but in very few (<5%) sporadic ARMS cases.

Alterations in genes encoding RB1 or proteins regulating RB1 function occur in sporadic ERMS and ARMS tumors, providing several mechanisms to alter RB1 signaling. Although small *RB1* mutations were not conclusively investigated in sporadic RMS, homozygous deletions were found in 22% (6/27) of ERMS and 10% (2/20) of ARMS cases (see Table 59-3).[66] A higher frequency of *RB1* gene alterations in ERMS is suggested by the finding of significantly lower RB1 expression in ERMS compared with ARMS tumors. As described earlier, 12q13-q14 amplification in a subset of ARMS cases results in overexpression of CDK4, which phosphorylates RB1 and contributes to RB1 functional inactivation. In another subset of RMS cases, homozygous deletions and/or point mutations occur in *CDKN2A* and *CDKN2B*, which encode inhibitors of CDK4 and CDK6.[35,67-69] These alterations occur in both ARMS and ERMS, with an overall homozygous deletion frequency of 13% (11/82) and a mutation frequency of 7% (6/88).

There is also evidence for genetic changes that alter the TP53 pathway in sporadic RMS tumors (see Table 59-3). In multiple studies examining a total of 159 RMS cases,

ARMS, Alveolar rhabdomyosarcomas; *ERMS*, embryonal rhabdomyosarcomas; *NA*, not available.
*RMS cell lines were not included in this compilation.
†Other includes Botryoid, pleomorphic, mixed, and unclassified cases.
‡In one ERMS case, both a HRAS and a NRAS mutation were detected.

12 missense mutations (8%) were detected in the *TP53* gene.[46,47,70-72] Although many cases were not subclassified for histopathologic subtype, mutations were found in both ARMS and ERMS.[46,47,71,73] Homozygous deletions involving *TP53* were also detected in a few cases.[73,74] In addition to these direct changes in *TP53*, changes in the TP53 pathway may be caused by *MDM2* gene amplification (described earlier), which encodes a protein that binds to and inactivates TP53. Finally, deletion of the *CDKN2A* locus (described earlier) also eliminates expression of p14ARF, which is a protein that normally blocks MDM2 function and stabilizes the TP53 protein.[69]

Activation of several additional signaling pathways is also implicated in sporadic RMS tumors (see Table 59-3). Mutation in the tyrosine kinase domain of the membrane receptor fibroblast growth factor receptor 4 *(FGFR4)* was detected in 15 of 171 (9%) RMS tumors, including 11 in 112 (10%) ERMS and 2 in 47 (4%) ARMS cases.[35,60,75] These mutations activate downstream signaling from FGFR4 and increase proliferation, invasion, and metastatic potential in mutation-bearing cells. Other genes in which mutations were found only in ERMS tumors include *PIK3CA* (3/57, 5%) and *CTNNB1* (2/57, 4%); these mutations will activate phosphatidylinositol-3-kinase and Wnt signaling pathways, respectively.[60,64] Although activation of the Hedgehog signaling pathway has been noted in a substantial subset of ERMS tumors, point mutations were not found in genes encoding several classic pathway components.[76-78] As a possible alternative explanation of this increased Hedgehog signaling, low-level gains of the *GLI1* locus were found in numerous ERMS cases.[35] Finally, *DICER1* mutations have been detected in 2 of 52 (4%) sporadic ERMS tumors and result in deregulated microRNA processing.[79,80]

Hypermethylation as an Alternative Mechanism of Gene Inactivation in Rhabdomyosarcoma

In a final set of genomic changes in RMS, genetic loci can be silenced by epigenetic events involving tumor-specific hypermethylation of CpG islands. The cytosine residues in CpG dinucleotides are ordinarily unmethylated in normal cells but can become methylated during

tumorigenesis, thereby altering the nearby chromatin structure and silencing transcription of associated genes. Studies of small numbers of RMS cases indicated that several genes often hypermethylated in other tumor types, such as *CDKN2A,* are not affected in a significant subset of RMS cases. However, hypermethylation of the CpG islands in the *RASSF1A, HIC1,* and *CASP8* genes was detected in both ARMS and ERMS tumors.[81-83] In contrast, there is evidence of differential methylation of the CpG islands in the *MYOD* and *PAX3* genes such that hypermethylation occurs in most ERMS cases and hypomethylation occurs in most ARMS cases.[84,85] A genome-wide approach also identified 140 promoter regions hypermethylated in at least four of ten RMS tumors compared with skeletal muscle, including genes implicated in development and tumorigenesis, such as *GATA6* and *HES5*.[86] Unsupervised hierarchical cluster analysis indicates that DNA methylation pattern correlates with RMS subtype. These hypermethylation events are generally associated with loss of expression of the corresponding proteins, providing an alternative nonmutagenic mechanism for inactivating genes and altering associated pathways.

APPLICATIONS OF MOLECULAR GENETIC APPROACHES TO DIAGNOSIS AND PROGNOSIS

Detection of Recurrent Gene Fusions

As described earlier, RT-PCR and FISH methodologies were developed to detect the *PAX3-FOXO1* and *PAX7-FOXO1* gene fusions in clinical material.[24-27] In contrast to Southern blot approaches, both RT-PCR and FISH can be applied to detect these fusions in small amounts of input tissue. Furthermore, both RT-PCR and FISH approaches have been developed for formalin-fixed paraffin-embedded tissues as well as fresh and frozen tissues. Another favorable feature of the RT-PCR assays is high technical sensitivity, which permits detection of micrometastatic spread of rare fusion-positive cells to tissues such as bone marrow.[87] Although FISH has lower technical sensitivity, a break-apart *FOXO1* FISH assay has simplified detection of *FOXO1* rearrangements resulting from either *PAX3-FOXO1* or *PAX7-FOXO1*.[41] In addition, break-apart *PAX3* and *PAX7* assays facilitate detection of variant fusions in ARMS cases that do not contain either of the two usual fusions.[27]

Pathologic and Clinical Differences between Fusion Subtypes

Clinical-molecular correlative studies revealed several differences between fusion-negative and fusion-positive tumors. In comparisons of outcome among the fusion subsets, the fusion-negative ARMS cases have a failure-free survival (FFS) and overall survival (OS) similar to ERMS cases and significantly better than fusion-positive ARMS cases.[37,88] There is a similar frequency of other parameters, such as unfavorable sites and metastasis, in ERMS and fusion-negative ARMS, and this frequency is lower in fusion-negative ARMS than in fusion-positive ARMS. Finally, in an examination of histopathologic parameters, nearly half of fusion-negative cases lack cystic foci and show totally "solid alveolar" architecture.[89]

Although there are no detectable histopathologic differences between *PAX3-FOXO1*– and *PAX7-FOXO1*–positive cases,[89] there are clinical differences between these two fusion-positive subsets. The OS rate in the *PAX7-FOXO1*–positive subset is superior to that in the *PAX3-FOXO1*–positive subset and similar to the OS rate in the ERMS and fusion-negative ARMS categories.[41,88,90] In contrast, failure free survival in the two fusion-positive subsets is similar. In addition to OS, there are other clinical differences between these two fusion-positive subsets. In particular, the *PAX7-FOXO1*–positive tumors are typically diagnosed at a younger age, more often present with an extremity primary tumor, and are associated with a lower frequency of local invasion and nodal metastasis.[28,41] A multivariate analysis of the contributions of prognostic parameters found that fusion status was an independent predictor of OS. A risk-based stratification incorporating fusion status, stage, and age has potential utility for stratifying the Children's Oncology Group (COG) intermediate-risk group into distinct subgroups.[90]

Gene Expression Profiling with Microarrays

Microarray-based analyses of genome-wide gene expression compared RMS with other pediatric tumors included in the differential diagnosis of small blue round cell tumors. Cases were clustered based on differences and similarities in expression patterns. Statistical analyses identified lists ranging from 20 to 93 genes that can correctly classify all tumors.[91-94] These lists contain genes specifically expressed in each tumor category, including muscle-specific and myogenesis-related genes that are specifically expressed in RMS. With the use of minimization strategies, the criteria needed for classification were reduced in size to lists ranging from 7 to 31 genes. To extend these findings, 39 genes were selected to design a multiplex RT-PCR assay, which generates findings comparable to the microarray platform.[95]

Microarray studies also developed classifiers for subsets within the RMS family. With the use of clustering algorithms, it was shown that the *PAX3-FOXO1*– and *PAX7-FOXO1*–positive subsets of ARMS cluster together, indicating no major expression differences between the two fusion-positive subsets.[37,50,96,97] In contrast, there was a striking difference in expression pattern between the fusion-positive and fusion-negative ARMS cases. There were four published cases with variant fusions: two clustered with fusion-positive tumors and two clustered with the fusion-negative tumors. These analyses also demonstrated a striking difference in expression pattern between ERMS and fusion-positive ARMS cases. Comparison of ERMS and fusion-negative ARMS cases did not reveal any recurrent expression differences between these two groups of fusion-negative RMS cases. Therefore, based on expression pattern, RMS cases can be divided into two major categories: the fusion-positive and fusion-negative cases. Furthermore, when viewed on a multidimensional scaling plot, the fusion-positive group showed a dense cluster whereas the fusion-negative group showed a cluster with more heterogeneous spread.

The fusion-negative RMS category is proposed to be further divisible into three novel subsets, which are related to expression of muscle differentiation and chromosome 11 genes.[50] A well-differentiated RMS subset expressed both gene sets, whereas a moderately differentiated RMS subset expressed the chromosome 11 genes with decreased levels of muscle differentiation genes. A final subset containing approximately 25% of ERMS tumors as well as undifferentiated sarcomas and non-RMS soft tissue tumors (NRSTS) did not express either gene set. In addition, tumors in this last subset had a fractional allelic loss (including 11p loss) similar to that in fusion-positive RMS tumors and twofold lower than that in the well-differentiated and moderately differentiated subsets. The significance of these subsets is highlighted by the finding of good, intermediate, and poor outcomes in well-differentiated, moderately differentiated, and undifferentiated sarcoma/NRSTS categories, respectively.

For prospective diagnosis of fusion-positive or fusion-negative RMS, genes differentially expressed between the two fusion subsets were identified to generate initial signatures ranging from 121 to 534 genes.[37,50,96,97] The genes preferentially expressed in fusion-positive tumors were overrepresented in PAX3-FOXO1 downstream targets (including genes involved in neurogenesis) and chromosome 6 genes, whereas the genes preferentially expressed in fusion-negative tumors were overrepresented in chromosome 8 genes. Additional statistical approaches identified minimal signatures consisting of 10, 5, or even 2 genes with predictive accuracy of 95% or greater.[50,97,98] To develop an assay applicable to formalin-fixed paraffin embedded samples, biomarkers were identified that correspond to differentially expressed genes with commercially available antibodies suitable for immunohistochemistry.[50,99] These efforts identified epidermal growth factor receptor (EGFR), fibrillin-2, and high-mobility group AT-hook 2 (HMGA2) as markers expressed in fusion-negative RMS cases and transcription factor AP-2β (TFAP2B) and P-cadherin as markers expressed in fusion-positive RMS cases. The combination of two markers for each RMS subset achieved specificity of 90% or greater and a sensitivity of 60% or greater.

Several microarray and other genomic approaches were used to identify fusion protein downstream targets. In one approach, transduction of *PAX3-FOXO1* or *PAX7-FOXO1* in an ERMS cell line modulated expression of 334 genes (266 increased and 68 decreased); 81 of these genes (24%) were also differentially expressed between fusion-positive and fusion-negative RMS tumors.[100] In the second approach, siRNA-mediated downregulation of *PAX3-FOXO1* in an ARMS cell line decreased expression of 1834 genes after 24 hours of treatment; only 51 (3%) of these genes overlapped the differential expression signature in RMS tumors.[101] In a final approach, ChIP-Seq analysis identified 1463 genomic regions bound to the fusion protein in ARMS cells; these genomic regions correspond to 24% of genes expressed at higher levels in fusion-positive RMS and 6% of the genes expressed at higher levels in fusion-negative RMS.[102] These findings indicate that only a fraction of expression differences between fusion-positive and fusion-negative tumors is directly attributable to the fusion protein; many of the expression differences may result from other genetic and environmental differences between these RMS subsets.

Microarray analysis also elucidated genes whose expression predicts outcome in RMS patients. In particular, Cox regression proportional hazards modeling of OS with RMS microarray expression data identified 15 or 34 gene sets whose aggregate pattern of expression was correlated with OS.[90,103] The performance of these two gene sets was high in the initial patient cohort and lower but still significant in a validation cohort. For the 34 gene set, this expression-based stratification of RMS cases was related to the current COG risk classification system. In addition, this expression-based stratification for both the 15- and 34-gene sets was also correlated with *PAX3-FOXO1* and *PAX7-FOXO1* fusion status. Multivariate analysis showed that these 15- or 34-gene sets were not independent predictors of outcome.

A hypothesis was also proposed that fusion protein downstream targets may predict outcome.[100] Starting with 81 target genes that were both modulated by exogenous fusion protein in ERMS cells and differentially expressed between the fusion-positive and fusion-negative tumors, Cox regression modeling elucidated a 28-gene predictor. An aggregate score calculated from expression of these 28 genes is predictive of OS in ARMS and independent of known prognostic variables. This finding suggests that modulation of downstream fusion protein target expression is associated with differences in biologic aggressiveness of ARMS.

Detection of Rhabdomyosarcoma in Sites Other Than Primary Tumor

Molecular markers in conjunction with high-sensitivity detection methodologies have been applied to screen for RMS dissemination in accessible and commonly involved sites such as bone marrow, peripheral blood, and lymph nodes (Table 59-4). In general, these approaches screen for molecular markers within cells to identify cases that are not detected by conventional radiology or pathologic examination. One strategy for minimal disseminated disease detection focuses on tumor-specific markers, such as *PAX3-FOXO1* and *PAX7-FOXO1*.[87,104] A second strategy, which is broadly applicable to all RMS subtypes, assays lineage-specific markers, such as myogenic markers of determination and differentiation (including MYOD1 and MYOG).[104-106] In a third strategy, sites of disease spread were assayed for proteins involved in metastatic pathways, such as CXCR4 and MET.[107] RT-PCR assays were developed to detect several of these markers and demonstrate analytical sensitivity in the range of one positive cell per 10^4 to 10^5 normal cells.[87,104,105] More recent PCR protocols use real-time technology to quantify the extent of disseminated disease and can thus monitor changes in disease load over time and compare results to an empirically determined clinical threshold. In addition to PCR assays, antibodies have been used to

detect various protein markers in immunocytochemical or flow cytometry assays.[106,107] These assays also have a high level of analytical sensitivity (~10^{-4}), which is significantly better than conventional morphology-based evaluation.

These minimal disseminated disease assays were applied to clinical material from RMS patients in several different settings (see Table 59-4). Multiple studies addressed the feasibility of detecting occult disease in bone marrow.[87,104,105] These studies showed that histologically positive bone marrows are consistently detected, regardless of the methodology or marker. For histologically negative marrows, various methodologies and markers detected submicroscopic disease, with the frequency tending to be higher for ARMS relative to ERMS. In ARMS, which often metastasizes to the bone marrow, the frequency of a positive result in a histologically negative marrow ranges from 15% to 60%. In ERMS, in which bone marrow is not a common site of metastasis, the frequency of a positive result in a histologically negative marrow ranges from 7% to 33%. The presence of these marrow-infiltrating RMS cells is not consistently associated with subsequent overt marrow involvement, suggesting that the marrow can act as a transitory reservoir for disseminated RMS cells.[107] Despite this finding, a significant association was found between poor outcome and detection of RMS cells in bone marrow; marrow involvement was associated with a significantly higher risk for recurrence (50% vs. 11%, $P = .011$) and poorer OS rate (47% vs. 92%, $P = .01$).[106] In addition to bone marrow, studies also evaluated peripheral blood samples at diagnosis, during treatment, and after treatment.[105,108] Comparison with outcome revealed that a positive result at the end of treatment was associated with poor outcome, and persistent positive results preceded a metastatic relapse.

Recent studies also examined expression of molecular markers in the serum or plasma. These markers include miR-206 and other muscle-specific miRNAs (see section below on microRNAs), which were measured by RT-PCR, and RMS-associated proteins, such as insulin-like growth factor–binding protein 2 (IGFBP2) and vascular endothelial growth factor (VEGF)- A (VEGF-A), which were assessed by enzyme-linked immunosorbent assay (ELISA).[109-111] The finding of higher abundance of these markers in the plasma or serum of RMS patients relative to normal controls indicates a possible use in noninvasive diagnosis. Furthermore, an application in disease monitoring is suggested by the finding of decreased levels after treatment. Finally, an association of plasma IGFBP2 levels with metastatic RMS suggests a potential role in patient stratification for risk-based therapy.

MOLECULAR AND CELLULAR BIOLOGY OF RHABDOMYOSARCOMA

Myogenic Pathways in the Tumorigenesis of Rhabdomyosarcoma

Based on the premise that RMS is related to the skeletal muscle lineage, the expression pattern of muscle-specific proteins has been extensively examined in RMS. In particular, many studies have focused on the family of myogenic transcription factors (MyoD, Myf5, myogenin, and MRF4) that are responsible in part for the determination of stem cells into myoblasts and then differentiation into myocytes. Assays of the corresponding genes detected RNA expression of *MYOD* and *MYF6* in all ARMS and ERMS tumors and RNA expression of *MYOG* (myogenin) and *MYF5* in all ARMS and most ERMS tumors.[112] Antibodies directed to MyoD and myogenin have proved to be suitable for immunohistochemistry on paraffin-embedded, formalin-fixed tissues.[113] With the use of these antibodies the vast majority of RMS cases (about 97% in a study of 956 cases) showed positive nuclear immunostaining for each protein.[2] Because positive staining also occurred in multiple cases of pleuropulmonary blastoma, the specificity of these reagents was estimated to be between 90% and 91%. There are differences between ARMS and ERMS tumors in the myogenin staining patterns such that most cells within an ARMS tumor stain positive, whereas fewer cells within an ERMS tumor stain positive. This differential staining between ARMS and ERMS has also been shown for MyoD. There is a statistical difference in the extent of MyoD or myogenin expression among the RMS subtypes, but there is still overlap. Hence the immunohistochemical pattern of these myogenic proteins is not sufficient to classify cases but may be helpful in selecting cases for further testing.

Functional studies in RMS cell lines determined that MyoD is not an active transcription factor in the RMS environment (Fig. 59-4).[114] In particular, although MyoD is able to bind DNA at its specific binding sites in RMS cells it is not capable of acting as a transcriptional activator on model genes with these DNA-binding sites. These

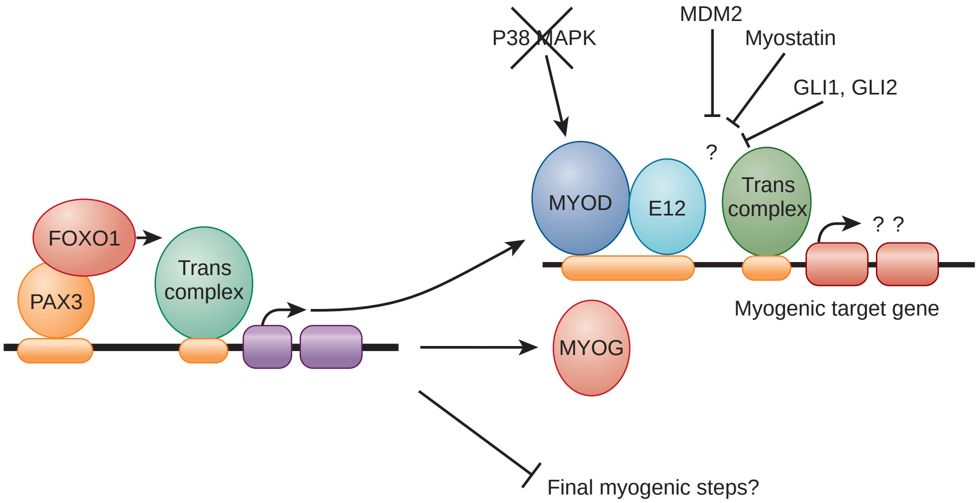

Figure 59-4 Influences on myogenic differentiation in ARMS. A model *PAX3-FOXO1* target gene is shown on the left, with PAX3-FOXO1 binding to a positive acting *cis*-element and interacting with the transcriptional machinery at the promoter to upregulate transcription of mRNA and ultimately increase production of the target protein. Two such targets are postulated to be MYOD and myogenin (MYOG). In turn, MYOD and its binding partner E12 bind to *cis*-elements of myogenic target genes and stimulate the transcriptional machinery to upregulate transcription of the corresponding mRNAs. In alveolar rhabdomyosarcoma (and embryonal rhabdomyosarcoma), various upstream changes can influence the transcriptional activity of the MYOD protein and thereby inhibit myogenic differentiation.

effects may contribute to the failure of RMS cells to undergo terminal differentiation. Various factors may contribute to this inhibition of transcriptional activation by MyoD. Experiments fusing RMS cell lines to a second normal cell line resulted in some instances in which the transcriptional activation block was overcome, suggesting that the RMS line was deficient in a *trans*-acting factor. In other instances, the block was not overcome by this cell fusion, suggesting a dominant-acting inhibitory factor. As an example of the former recessive scenario, the p38 mitogen-activated protein kinase (MAPK) pathway is deficient in some RMS cell lines, resulting in the absence of an essential activator of MyoD during myogenic differentiation.[115] Examples of the latter dominant scenario include amplification of *MDM2* in an RMS cell line that inhibited MyoD activity by a mechanism involving competition for the transcription factor Sp1[116,117] and upregulation of musculin and a novel splice variant of E2A that inhibited MyoD activity by competing for heterodimer formation and preventing formation of functional MyoD:E-protein heterodimers, required for the switch to differentiation.[118] In addition, increased expression of the negative muscle growth regulator myostatin, which is found in both ERMS and ARMS, is also capable of inhibiting MyoD-mediated transcriptional activity, possibly via Smad3 interactions.[119] In RMS associated with activation of the Hedgehog pathway, expression of the transcription factor GLI1 or GLI2 inhibits MyoD-mediated transcriptional activation by reducing heterodimerization with its partner E12 and DNA binding.[120] Finally, as discussed in the later section "Epigenetic Regulation," MyoD activity can also be inhibited by decreased expression associated with KMT1A methyltransferase activity.[121]

The identification of *PAX3-FOXO1* and *PAX7-FOXO1* gene fusions in ARMS also highlight PAX3 and PAX7 as important proteins in normal and aberrant myogenic transcriptional control. In murine systems, both Pax3 and Pax7 are involved in early embryonic development of cells giving rise to axial musculature, and Pax3 also has a necessary role in the early embryonic development of the limb musculature.[122-124] In the adult mouse, Pax7 has an important role in the development of the major population of myogenic satellite cells and Pax3 is expressed in satellite cells in a subset of muscles.[125,126] This developmental biology of *PAX3* and *PAX7* is relevant to ARMS tumors, which express *PAX3* or *PAX7* as a fusion with *FOXO1*,[127] and to ERMS tumors, which express wild-type *PAX3*, *PAX7*, or both.[128]

The wild-type and fusion PAX proteins can variably affect the myogenic status of the cells expressing them. When wild-type Pax3 is introduced into explanted embryonic tissues, it can activate the myogenic program as shown by expression of MyoD, Myf5, and myogenin as well as myogenic differentiation products.[129] In contrast, Pax3 could not induce this myogenic program in NIH 3T3 murine fibroblasts, suggesting that this murine fibroblast represents a less permissive environment.[130] Studies of the PAX3-FOXO1 fusion protein have demonstrated a range of activities on the myogenic program (see Fig. 59-4). First, studies focusing on the *MyoD* and *myogenin* promoters provide evidence that both of these genes are transcriptional targets of PAX3-FOXO1. Of two studies of NIH 3T3 cells, one indicated that PAX3-FOXO1 induced the myogenic program, including the upstream products MyoD, myogenin, Six1, and Slug as well as downstream myogenic products, such as troponins and myosin light chain.[130] However, a second study of NIH 3T3 cells demonstrated induction of the upstream products MyoD, myogenin, and desmin but no induction of the downstream product myosin heavy chain.[131] In contrast to these findings, transduction of *PAX3-FOXO1* into two additional murine fibroblast lines (10T1/2 and Plus) resulted in expression of both upstream and downstream myogenic products and fusion into multinucleated myotubes. In contrast, introduction of *PAX3* or *PAX3-FOXO1* into two myogenic cell lines, C2C12 myoblasts and MyoD-expressing 10T1/2 cells, inhibited terminal myogenic differentiation after stimulation of differentiation by growth factor withdrawal.[132] *PAX3-FOXO1* was more potent than wild-type *PAX3* in this phenotypic activity. Finally, repression of *PAX3-FOXO1* expression in human ARMS cell lines with RNA interference (small interfering RNA [siRNA] or short hairpin RNA [shRNA] constructs) results in decreased proliferation without apparent apoptosis, decreased motility and invasion, and increased differentiation as demonstrated by morphologic and myogenic gene and protein expression.[101,133,134] This finding indicates that *PAX3-FOXO1* normally represses expression of this myogenic pathway in this cell type.

The finding of both stimulatory and inhibitory effects of PAX proteins on myogenic events may be explained by the hypothesis that these wild-type or fusion PAX proteins facilitate entry into the myogenic pathway and variably inhibit the final steps of the pathway depending on the cellular environment. In support of this hypothesis, data suggest that PAX3-FOXO1, by inducing MyoD expression but attenuating its activity, and inducing FGFR expression to block differentiation, simultaneously stimulates but blocks completion of myogenesis.[135] This intermediate commitment to differentiation may be partially explained by recent studies in which expression of *PAX3-FOXO1* in muscle satellite cells did not inhibit expression of MyoD but did inhibit expression of MyoD target genes.[136]

MicroRNAs

Although decades of study shed light on the intrinsic cellular signaling pathways and extrinsic microenvironmental stimuli that control skeletal muscle differentiation during embryogenesis, postnatal life, and muscle repair, it was not until 2005 that another layer of control was identified. In work examining the spatiotemporal control of cardiogenesis, it was discovered that specific microRNAs were expressed in cardiac and skeletal muscle and served to balance proliferation and differentiation of muscle precursor cells.[137] Since that time, a great deal of information on these small noncoding RNAs that enable the regulation of protein dosage through binding to 3′ ends of mRNA and affecting stability or translation to protein has been gathered and understood not only in the framework of normal skeletal myogenesis but also in tumors related to the skeletal muscle lineage such as RMS.

MicroRNAs influencing skeletal myogenesis can generally be divided into myomirs (miRs specific to skeletal and cardiac muscle) and nonmyomirs (miRs expressed in nonmuscle tissue but that can also be found in muscle.) The myomirs (nomenclature miR-1 to miR-206, which includes the miR-133 group) are encoded in bicistronic clusters on chromosomes 6, 18, and 20 and control such diverse developmental processes as somite organization, muscle precursor cell migration, survival, differentiation, fusion, and cross talk with epigenetic processes that control differentiation (see next section). Similar to other human cancers, RMS tumors are noted to have lost expression of miRs and their tumor suppressive properties. When miR-206 is expressed in human RMS cells, xenograft growth is halted and accompanied by differentiation,[138] presumably by the orchestrated downregulation of hundreds of miR-206 target genes,[139] including *MET*.[138] Mir-206 expression levels also correlate with clinical behavior of RMS.[140] Regarding the nonmyomirs, the reader is referred to two reviews on microRNAs and their role in RMS.[141,142] For example, miR-185 suppresses RMS tumor growth and progression by targeting the *Six1* oncogene[143] (see later discussion under "Metastatic Pathways in Rhabdomyosarcoma").

Finally, as was discussed in the section on "Rhabdomyosarcoma in Cancer Predisposition Syndromes," germline or somatic mutations of DICER1, the enzyme that cleaves pre-microRNA to mature microRNA, have been found associated with ERMS.[80,144,145] To date these mutations appear to be in the RNase IIIb domain, resulting in a decrease in its activity.

Epigenetic Regulation

Although the block to myogenic differentiation in RMS cells has been apparent for decades, only recently is there insight into some of the epigenetic changes enforcing this inhibition. As mentioned earlier, whereas the muscle-specific transcription factor MyoD can bind DNA in RMS, some targets fail to activate. For example, although MyoD binds similarly at the genome-wide level in both normal and RMS (in this case the human embryonal RMS cell line RD was studied), in RMS there is a subset of genes to which MyoD binds poorly and thus does not activate.[146] This subset includes the transcription factors *MEF2C, RUNX1, JDP2,* and *NFIC,* found expressed at lower levels in RMS compared with normal muscle cells. There was also differential DNA accessibility, including changes in DNA methylation status. Therefore it has become clear that epigenetic changes contribute as much to RMS as changes in the DNA sequence itself. Below are summarized some of the epigenetic changes found in RMS, including changes in DNA methylation (introduced earlier in "Hypermethylation as an Alternative Mechanism of Gene Inactivation in Rhabdomyosarcoma"), changes in histone methylation, and changes in nucleosome positioning.

Methylation of gene promoters at CpG islands by DNA-specific methyltransferases serves to silence expression of target genes. Thus it would follow that tumors should demonstrate different DNA methylation profiles compared with nonmalignant tissue, and indeed a study of the genomes of RMS compared with normal skeletal muscle showed this to be the case.[147] In both ERMS and ARMS, genes involved in development and differentiation were hypermethylated compared with normal skeletal muscle. However, there were also differences between ERMS and ARMS, with ARMS showing more hypermethylation of Polycomb target genes (see later.) As methods to improve the speed and resolution of the detection of DNA methylation patterns improve, further changes are expected to be identified.

Methylation of lysine residues in histones by Polycomb group remodeling complexes (known as PRC1 and PRC2) also serves to silence chromatin, by influencing nucleosome formation and function. Although this process occurs in a carefully controlled manner during development, if Polycomb complexes are inappropriately recruited to target genes or inappropriately activated due to component mutation, impaired commitment to cell lineage or a frank block in differentiation can ensue, resulting in a primitive cellular phenotype. For example, in both ERMS and ARMS the NF-κB-YY1-mir-29 regulatory circuit that ordinarily controls skeletal myogenesis is usurped; YY1 recruits PRC2 to silence target genes including *MIR29*, so that muscle differentiation cannot occur.[148] In ARMS, PAX3-FOXO1 transcriptionally activates JARID2 expression, which recruits PRC2 to the promoter regions of target genes including *MYOG* and *MYL1*, again impairing differentiation.[149] Recently, there has been some focus on the catalytic component of PRC2 known as the EZH2 methyltransferase. EZH2 was found upregulated at the protein level in RMS tumors[150]; and in loss-of-function studies in RD cells, silencing of EZH2-induced MyoD activation and partial reversal of the tumorigenic phenotype.[151]

There are also methyltransferases independent of Polycomb group remodeling complexes that appear dysregulated in RMS. For example, the histone methyltransferase KMT1A (formerly known as Suv39h1), which methylates histone H3 on the lysine 9 residue, represses myogenic gene expression directed by MyoD.[152] In ARMS this keeps the cells in an undifferentiated state. In support of its presumed oncogenic role, suppression of KMT1A by siRNA decreases ARMS cell and xenograft growth.[121] In independent studies, a screen for tumor suppressors in a Kras- driven model of zebrafish ERMS revealed that point mutations in KMT1A suppress RMS formation.[153]

Regarding the epigenetic changes that occur in response to nucleosome repositioning, components of the SWI/SNF chromatin remodeling tumor suppressor complex have been found mutated in RMS. An early hint of the involvement of the SWI/SNF complex was in the study of TPA-mediated differentiation of RD cells, which was shown to work by recruiting proteins including BRG1 (a subunit of SWI-SNF) to the myogenin promoter,[154] driving differentiation. Later work showed that the BAF53a subunit of SWI/SNF is not downregulated in RMS and thus contributes to a differentiation block.[155]

Role of Insulin-like Growth Factors in Rhabdomyosarcoma

Insulin-like growth factor 2 (IGF-2) is an important growth factor during the fetal period and is highly expressed in fetal skeletal muscle but not detectably expressed in adult skeletal muscle.[156] High-level IGF-2 expression in murine myoblasts results in an increased proliferative rate, impaired myogenic differentiation, and anchorage independence, indicating a potential role of IGF-2 in neoplasia of the myogenic lineage.[157] In accord with these findings, IGF-2 is highly expressed by both ERMS and ARMS tumors as well as in derived RMS cell lines[158] (Fig. 59-5). In addition to the growth factor, both RMS subtypes express the IGF-1 receptor (IGF-1R), which is a cell surface receptor for IGF-2 as well as IGF-1. This simultaneous expression of growth factor and receptor creates an autocrine loop that stimulates the growth and motility of RMS cells. No mutations have been detected in these genes; hence this autocrine situation may reflect the fetal muscle expression pattern that is maintained or induced by the other genetic alterations. The growth response is mediated through IGF-1R, whereas the motility response is mediated through the distinct IGF-2/mannose-6-phosphate receptor.[159] Numerous studies have explored different strategies for interfering with the action of IGF-1R. These strategies include an antibody directed to this receptor, a kinase-deficient mutant that acts as a dominant negative, and an antisense construct directed to this receptor.[160-162] Each of these strategies decreases the response of the cells to IGF-2 stimulation, inhibits cell growth and anchorage independence in culture, and inhibits tumorigenicity in vivo. Exploitation of this downregulation for preclinical and clinical studies is described in "Preclinical Investigation of Emerging Drug Targets for Rhabdomyosarcoma" and "Clinical Research in Rhabdomyosarcoma".

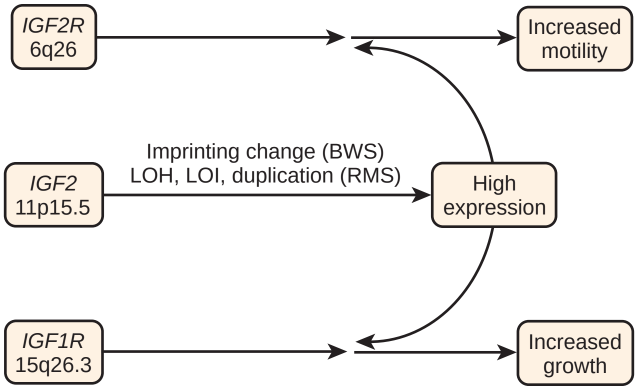

Figure 59-5 Changes in IGF pathway and associated phenotypic consequences in RMS. The three involved genes and their chromosomal locations are shown on the *left*. Genetic or epigenetic changes are indicated above the *horizontal arrows*. Changes in expression or phenotype are indicated on the *right*. *BWS,* Beckwith-Wiedemann syndrome; *LOH,* loss of heterozygosity; *LOI,* loss of imprinting.

As described earlier, the *IGF2* gene is located in the 11p15.5 chromosomal region, which is implicated in allelic loss events that occur in RMS tumors and in genetic alterations in the inherited disorder BWS, which predisposes to malignant tumors, including RMS.[49,52,53] The *IGF2* gene is part of an imprinted region and is preferentially expressed from the paternally inherited alleles. The result of the allelic loss events and genetic changes in BWS is loss of the nonexpressed maternal allele and maintenance or gain of the expressed paternal allele. In addition to these genetic changes, other alterations of 11p15 involving the *IGF2* locus have been identified in both ARMS and ERMS tumors. In one study of 11 RMS tumors (including 4 ARMS tumors, 6 ERMS tumors, and 1 RMS tumor of uncertain classification), 1 ARMS and 3 ERMS cases demonstrated evidence of duplication of an *IGF2* allele.[163] Furthermore, although *IGF2* is normally expressed from only one allele, loss of imprinting can occur and result in a biallelic expression pattern. In RMS, loss of imprinting at the *IGF2* locus has been observed in 5 of 12 ERMS and 9 of 16 ARMS cases.[163-165] These duplication or imprinting changes increase the number of active *IGF2* alleles and may thereby contribute to the high expression of *IGF2* mRNA and protein found in RMS tumors.

In mammalian cells, the subcellular localization of the wild-type FOXO1 (previously FKHR) and related FOXO3 and FOXO4 proteins is regulated by a PI3K-AKT (PKB-dependent) signaling pathway that is activated by survival- and growth-related signals such as IGF-2.[166] In this signaling pathway, AKT-mediated phosphorylation of FOXO proteins leads to protein transfer from the nucleus to the cytoplasm and thus inactivates transcriptional function. Of the three AKT phosphorylation sites in FOXO1, two are retained in PAX3-FOXO1 and PAX7-FOXO1. If the fusion proteins are regulated by this pathway, the high level of IGF-2 in ARMS cells would cause these proteins to be phosphorylated and sequestered in the cytoplasm. However, experiments show that PAX3-FOXO1 is retained in the nucleus and is transcriptionally active in cultured cells in the presence of active AKT and in ARMS cells.[167] All studies performed to date find that PAX3-FOXO1 is constitutively nuclear, even in the presence of activated AKT.[167,168] However, whereas one transfection study did not find any changes in PAX3-FOXO1 transcriptional activity in the presence of activated AKT, a more recent study of a murine model of ARMS found that AKT hyperactivation results in PAX3-FOXO1 phosphorylation and decreased transcriptional activity. Studies in human ARMS cells are needed to resolve these issues and discern whether AKT activation has any effect on PAX3-FOXO1 function.

Modulation of Growth and Apoptotic Pathways by Fusion Oncoproteins

Gene transfer experiments have investigated specific functions of the PAX3-FOXO1 and PAX7-FOXO1 fusion proteins and suggest that these proteins exert an oncogenic effect through multiple pathways. In initial studies of growth control, transduction of PAX3-FOXO1 into murine NIH 3T3 or chicken embryo fibroblasts resulted in transforming activity, whereas wild-type Pax3 did not transform these cells.[169,170] In a complementary study, a protein consisting of the N-terminal region of PAX3 fused to the KRAB transcriptional repression domain reverted the transforming activity of ARMS cells in culture and suppressed tumor formation of ARMS cells in mice.[171] In mutagenesis analyses, the homeodomain but not the paired box is needed by PAX3-FOXO1 for transformation; thus target genes with paired box binding sites may not be required for cellular transformation. In addition, transforming activity is activated when the VP16 activation domain is substituted for the C-terminal domain of PAX3, suggesting that other activation domains can mimic the effect of the C-terminal FOXO1 domain.[172]

More recent studies indicate that there is an antagonistic balance between transforming activity and growth-suppressive or toxic activity in many cell types in which PAX3-FOXO1 is expressed.[173,174] Transforming activity is optimally exerted at low expression levels of exogenous fusion protein. In contrast, at higher expression levels, comparable to the levels in human ARMS tumors, PAX3-FOXO1 causes cell death or growth suppression in various nontransformed cell lines. Therefore human ARMS cells can tolerate these high “physiologic” expression levels, whereas the non-ARMS cells do not tolerate these higher levels. The hypothesis proposed is that additional genetic alterations are necessary in ARMS to attenuate the toxic and growth-suppressive effects of the fusion protein. One such event may be inactivation of the *CDKN2A* tumor suppressor gene that collaborates with PAX3-FOXO1 to permit primary human skeletal muscle cell precursors to bypass the senescent growth arrest checkpoint.[175] It is noteworthy that mutation studies show that the growth suppressive and toxic activity is at least partly dependent on an intact paired box but does not require an intact homeodomain.[173] These findings suggest that there may be two separate sets of target genes mediating the transforming and toxic phenotypes as a result of the complex function of the PAX3-FOXO1 DNA-binding domain.

Despite the ability of PAX3-FOXO1 to induce toxic effects when introduced into many cultured cells, an important function of the PAX3-FOXO1 oncoprotein in ARMS cells is maintenance of cell viability by inhibiting apoptosis. Treatment of ARMS cells with either an antisense oligonucleotide directed against the *PAX3* translational start site or with siRNAs directed against the 5′ *PAX3* region resulted in a decrease in PAX3-FOXO1 protein expression.[101] This expression change was associated with a significant decrease in cell number as well as with morphologic and biochemical characteristics of apoptosis. Similarly, expression of a tamoxifen-inducible PAX3-KRAB construct in ARMS cells demonstrated evidence of apoptosis when induced in low serum conditions or tumor xenografts.[176] One downstream transcriptional target of PAX3-FOXO1 that at least partially mediates this apoptotic function is the gene that encodes the transcription factor TFAP2B.[101] The functional role of TFAP2B is indicated by the induction of apoptosis in ARMS cells when this gene is downregulated by siRNA and by the prevention of apoptosis mediated by siRNA directed against the 5′ *PAX3* region when a construct constitutively expressing TFAP2B is introduced into ARMS cells.

Metastatic Pathways in Rhabdomyosarcoma

Early studies of RMS metastasis examined subclones of the RD ERMS cell line. The metastatic capacity of different subclones did not correlate with the tumorigenic or proliferative capability of the subclones.[177] After exposure to conditions that stimulate myogenic differentiation, some subclones showed increased differentiation manifested by an increased fraction of myosin-positive cells.[178] Although proliferative capability did not correlate with this in vitro differentiation, the metastatic efficiency was reduced in subclones demonstrating differentiation.

Additional studies with the RD line showed that its metastatic efficiency is affected by alterations of cell surface molecules. In the case of the cell surface glycoprotein NCAM (neural cell adhesion molecule), this protein is posttranslationally modified by the addition of polysialic acid on its extracellular domain.[179] When the enzyme endoneuraminidase-N was injected intraperitoneally to cleave the polysialic acid from the surface of intraperitoneally implanted RD cells, there was a decrease in the frequency of lung and liver metastases. When the integrin VLA-2 (α2β1) that is not normally expressed by RD cells was introduced into these cells, there was increased adhesion to collagen and laminin in vitro and more metastatic foci in mice after either intravenous or subcutaneous injection.[180]

Among the various RMS subtypes, there are differences in matrix metalloproteinase (MMP) expression that may contribute to differences in metastatic behavior. Immunohistochemical analysis of 5 MMPs in 33 RMS cases found higher expression of MMP1, MMP2, and MMP9 in ARMS than in ERMS cases.[181] After confirming the higher MMP2 expression in ARMS in a comparison of ARMS and ERMS cell lines, the high MMP2 expression was correlated with more invasive behavior in the ARMS cell lines.[182] In a human RMS cell line with spontaneous metastatic progression, there was upregulation of MMPs and downregulation of tissue inhibitors of metalloproteinases.[183] Finally, attachment of RMS cells to fibronectin results in increased MMP2 expression and in vitro invasive behavior along with increases in COX-2 expression and prostaglandin E_2 production.[184] Treatment with exogenous prostaglandin E_2 can recapitulate this effect and increase MMP2 expression at the level of the MMP2 promoter. In contrast, treatment of cells with COX-2 inhibitors can reverse the fibronectin effects on MMP expression and invasive behavior. Another soluble factor released by RMS cells is heparanase, which is found upregulated in several human RMS cell lines. Heparanase cleaves heparan sulfates, thus releasing and likely making more bioactive heparan-bound growth factors. shRNA-mediated suppression of heparanase in RD and Rh30 cells (a commonly studied human ARMS cell line) inhibited their invasive properties as assessed by Matrigel invasion assays. Parallel studies examining heparanase mRNA expression in human tumor samples and human serum in order to validate the upregulation were suggestive but not statistically significant because total numbers were small and error bars wide, thus suggesting that further studies will be required.[185]

Three cell surface receptors, MET, CXCR4, and LIFR, are expressed in RMS and function in signaling pathways that impact metastatic behavior[186-188] (Fig. 59-6). Although *MET* and *CXCR4* genes are downstream targets of the PAX3-FOXO1 fusion protein, all three genes are expressed in both ARMS and ERMS tumors. CXCR4 is a G-protein–coupled chemokine receptor whose ligand is stromal derived factor-1 (SDF1), whereas MET is a member of the tyrosine kinase family of receptors whose ligand is hepatocyte growth factor/scatter factor (HGF/SF). Finally, leukemia inhibitory factor (LIF) binds to a heterodimeric membrane receptor composed of the LIF-specific LIFR and the gp130 receptor chain, which is also used as the receptor for interleukin (IL)-6, oncostatin M, and several other cytokines. All three ligands are secreted by the bone marrow, an important site of ARMS metastasis. The CXCR4-SDF1 signaling pathway is involved in the homing of normal cells to hematopoietic sites, and the MET-HGF/SF signaling pathway is involved in the

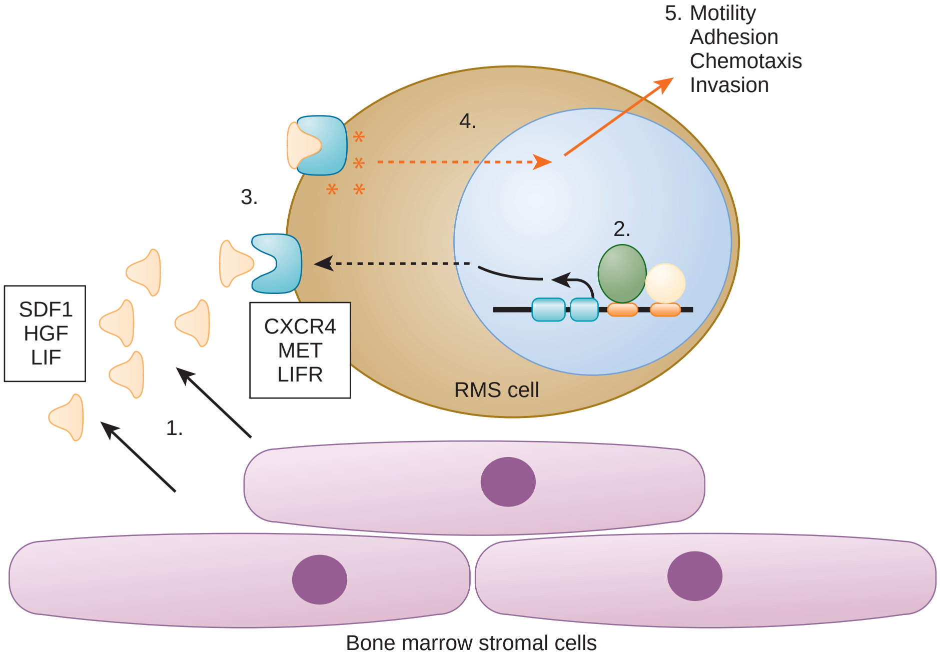

Figure 59-6 Role of secreted protein mediators in metastatic behavior of RMS cells. Bone marrow stromal cells secrete various protein mediators, including SDF1, HGF, and LIF (step 1). The RMS cells transcribe genes and then express cell surface receptors for these protein mediators (step 2). Binding of protein mediators to cognate receptors (step 3) activates various signaling pathways in the RMS cells (step 4). These signaling pathways ultimately modulate expression pathways in the nucleus that result in phenotypic changes (step 5).

proliferation and motility of various cell types. The LIF-LIFR signaling pathway has a variety of roles in multiple tissues, including proliferation of hematopoietic cells and muscle satellite cell production. For these reasons, usurpation of these signaling pathways has been proposed in the metastasis of various cancers.

Cell culture studies have explored the influence of CXCR4-SDF1, MET-HGF/SF, and LIFR-LIF signaling on the metastatic behavior of ARMS cells. SDF1, HGF, or LIF treatment of RMS cell lines induced cell culture changes in relevant properties, including motility, adhesion, chemotaxis, and invasion. In an in vivo experiment, more ARMS cells than ERMS cells are chemoattracted to and seed lethally irradiated bone marrow in association with the upregulation of HGF and SDF1 in irradiated bone marrow stroma. In addition, a selected ARMS subclone that preferentially responds to LIF demonstrates increased seeding of bone marrow, liver, and lymph nodes after intravenous injection and increased cells in bone marrow and lung 6 weeks after intramuscular injection. Recently, another receptor for SDF-1 called CXCR7 has been identified. This receptor binds not only SDF-1 but also interferon-inducible T-cell α chemoattractant (ITAC) chemokine. It is expressed in both ARMS and ERMS cells and appears to be independent from CXCR4, suggesting that CXCR4-SDF-1 axis targeting alone may not be enough.[189] Finally, as models of pathway-specific potential therapeutic strategies, a CXCR4-specific inhibitor blocked SDF1-directed adhesion and chemotaxis in ARMS cells, an siRNA directed against LIFR inhibited in vivo metastasis of ARMS cells, and suppression of MET receptor by shRNA in RMS cells decreased the migratory response in vitro.[190]

Recently, three additional cell surface receptors including IL-4 receptor-α (IL-4Rα), FGFR4 (discussed in "Oncogene and Tumor Suppressor Gene Mutations in Rhabdomyosarcoma"), and cannabinoid receptor 1 (CNR1) have been implicated in RMS metastasis. IL-4Rα is found upregulated in human and murine ARMS, and blockade by a neutralizing antibody inhibited both lymphatic and hematogenous metastasis in a genetically engineered murine model of ARMS.[191] Because there are neutralizing antibodies to IL-4R (and cognate ligands IL-4 and IL-13) in clinical use for nononcologic human diseases, this may be a feasible approach toward blocking RMS metastasis. FGFR4 gain of function (K535 and E550 tyrosine kinase domain) mutants enhanced the metastatic phenotype when expressed in both murine RMS cell lines and NIH 3T3 cells, as assessed by lung metastasis burden in xenograft assays.[75] Lastly, CNR1, which is also a PAX3-FOXO1 target, was shown to be dispensable for PAX3-FOXO1–driven cell proliferation and transformation but required for invasion and metastasis. In transformed primary mouse myoblasts expressing PAX3-FOXO1, either genetic or pharmacologic suppression of CNR1 reduced cell invasion in vitro and lung metastasis in vivo.[192]

Studies of a murine metastatic RMS model system elucidated an important pathway involving the *Vil2* (encoding Ezrin) and *Six1* genes. In this model system, RMS tumors developed in transgenic mice that were deficient in *CDKN2A (Ink4/Arf)* and overexpressed *HGF/SF*.[193] In a comparison of gene expression profiles of highly and poorly metastatic cell lines derived from this system, 44 differentially expressed genes were identified (28 overexpressed and 16 underexpressed in highly metastatic cells), including the overexpressed genes *Vil2* and *Six1*.[194] Ezrin is an adhesion molecule and member of the ERM family that promotes cytoskeletal reorganization in pathways linked to survival, motility, invasion, and adherence. Six1 is a homeodomain-containing transcription factor involved in the development of several lineages, is a downstream target of PAX3-FOXO1 in NIH 3T3 cells, and is expressed by ARMS cells.[130] Furthermore, the gene encoding Ezrin is a direct transcriptional target of Six1.[195] These gene expression relationships were confirmed by RMS tumor studies in which both genes were generally expressed at higher levels in fusion-positive RMS tumors than in fusion-negative RMS tumors.

Expression of *Vil2* and *Six1* in RMS tumors was correlated with clinical stage, which is consistent with a role in tumor progression and metastatic behavior.[194] There is direct proof of this role: transfer of either gene into low metastatic RMS lines from the HGF transgenic system caused increased metastatic activity. Similarly, when expression of either protein was suppressed by shRNA or repressed by a dominant-negative inhibitor, metastatic activity in the highly metastatic lines decreased. Finally, Ezrin is needed for Six1 to exert its metastatic function, thus further confirming that Ezrin acts downstream of Six1.[195] These studies provide the framework of a pathway that leads from the fusion proteins to Six1 to Ezrin to metastatic activity.

There are surely additional genes and proteins supporting the metastatic phenotype in RMS, and to this end a European collaborative group evaluated in RMS the expression of genes known to support metastasis using an Affymetrix approach.[196] After examining 19 primary human RMS tumor samples, they focused on two genes known as *LMO4* and *FOFOXF1*. Although they did not evaluate for expression of the protein products of these genes in RMS samples, they did assess their role in metastasis by showing that siRNA suppression of these genes in RD and Rh30 cells decreased migration as assessed by Matrigel invasion.

PRECLINICAL INVESTIGATION OF EMERGING DRUG TARGETS FOR RHABDOMYOSARCOMA

Preclinical Models to Study Rhabdomyosarcoma Tumorigenesis

Human Tumor Cell Xenografts in Immunodeficient Mice

Although the identification of mutations and/or dysregulated signaling in RMS is accelerating, the value of these entities as therapeutic targets must be evaluated in preclinical models before application in humans. The original models to study cancer treatments other than in cell lines were xenograft models, in which human cell lines were injected as xenografts into immunocompromised mice. Historically for RMS this began at St. Jude's Research Children's Hospital in the 1980s and has evolved into the Pediatric Preclinical Testing Program (http://pptp.nchresearch.org/). This program is a large-scale effort to systematically evaluate new agents against a panel of human RMS and other pediatric cancer cell lines by testing novel drugs against not only classic oncogene and tumor suppressor pathways including TP53 and receptor tyrosine kinases (RTKs) but also against newly identified targets found dysregulated in childhood cancer. Recently, the feasibility of adding radiation therapy to the Pediatric Preclinical Testing Program was demonstrated, using RMS as a pilot.[197]

There are obvious advantages to examining the efficacy of novel agents against pediatric tumor cell lines, including that they are of human origin and have been validated in prior biologic studies. But there are disadvantages as well, including that many cell lines have been passaged in culture for decades, acquiring genetic changes not representative of the original tumor. There is also the practical problem of cell line annotation[198]; however, with the development of methods to fingerprint cell lines, identification has been more reliable. Finally, the intrinsic property that enables evaluation of human cell lines in a whole murine organism— their immunodeficient state—does not permit the evaluation of the role of the immune system in tumorigenesis, a problem that can be overcome by the use of genetically engineered mouse models.

Genetically Engineered Murine Models of RMS

With the advent of genetic manipulation of the murine genome, it is now possible to examine the genesis and pathophysiology of RMS at the organism level. Indeed there are more than two dozen genetically engineered murine models that give rise to RMS. The earliest models were serendipitously discovered, for example that ERMS occurs in TP53 knockout mice or SV40 transgenic mice. Later models were deliberate in their design and incorporated genetic lesions found in RMS, including overexpression of the cMET signaling pathway or *PAX3-FOXO1* fusion gene. These and others are reviewed elsewhere.[199] More recently, sophisticated models have emerged in which Cre-Lox (or Flp-Frt) recombinase technology has been harnessed to turn on or turn off expression of specific genes or negative regulatory components such as shRNAs. This has been especially useful in examining the cells of origin of RMS, which may range from an undifferentiated mesenchymal stem cell to the myonucleus of a differentiated myofiber.[200] These approaches have led to some surprising discoveries, such as the finding that RMS can arise from the adipocyte lineage[201] and that ERMS is on a continuum with a common adult sarcoma known as undifferentiated pleomorphic sarcoma.[202] Last, these genetically engineered mouse models have also been useful as additional models for preclinical studies, such as the *PAX3-FOXO1*–based ARMS model.[203]

Lower Eukaryote Models of RMS

Although murine models have been the mainstay of modeling human cancer including RMS, lower organisms including zebrafish *(Danio rerio)* and the fruitfly *(Drosophila melanogaster)* are more amenable to genetic manipulation and screening and contribute a unique understanding of RMS genesis and metastasis. For example, zebrafish models of ERMS[204] have been useful for in vivo imaging of tumor-propagating cells and their properties[205] and understanding the impact of oncogenic RAS expression at different stages of muscle development.[206] *Drosophila* models of ARMS have provided insight into the pathophysiology of *PAX-FOXO1* fusion genes[207] and the role of defective myoblast fusion in RMS.[208]

A comprehensive listing of RMS animal models and their utility is available.[199] Along with the xenograft and genetically engineered mouse models, these models have enabled testing of pharmacologic agents in a preclinical fashion before to moving to phase I clinical trials. Below are listed some examples of agents that have been tested in a variety of in vivo preclinical models.

Inhibitors of Receptor Tyrosine Kinases

RTKs are embedded in the cellular plasma membrane and transmit signals from the environment to the cell interior. When a ligand binds to an RTK, dimerization occurs and this leads to internal phosphorylation events and signaling through a variety of canonical intracellular signaling pathways such as AKT, MAPK, mammalian target of rapamycin (mTOR), and many others. Because RTKs are at the cell surface, they can be blocked with interfering antibodies (or their ligands can be inhibited with neutralizing antibodies). Given the expansion in our understanding of the RTKs that are dysregulated or upregulated in RMS,[209] there are several monoclonal antibodies that have been evaluated in RMS. The prototype was a monoclonal targeting IGFR-1, known as figitumumab (previously CP-751871).[210] This agent not only blocked binding of ligand to the IGFR-1 but also downregulated the receptor, suppressed signaling to AKT, inhibited tumor-derived VEGF, and synergized with rapamycin. Several other studies followed, including testing of other anti–IGFR-1 monoclonal antibodies,[211,212] some of which advanced to clinical trials. However, tumor cells were able to activate bypass routes, rendering resistance to IGFR-1 blockade. Bevacizumab, a monoclonal antibody to VEGF, has been evaluated in a phase II clinical trial for RMS (see "Clinical Research in Rhabdomyosarcoma"). Still in development and preclinical testing are monoclonal antibodies to FGFR4[213] and NCAM,[214] both upregulated in a significant percentage of RMS tumors and implicated in RMS metastasis (see "Metastatic Pathways in Rhabdomyosarcoma"). Other new agents are also being considered for RMS.[215]

Given their enzymatic activity, RTKs can also be inhibited with small molecules. In a manner similar to the prototype small molecule imatinib, which was developed to inhibit the BCR-ABL fusion protein in chronic myelogenous leukemia,[216] there are also small molecule inhibitors being evaluated for RMS-associated RTKs. An early example was BMS-754807, an oral small molecule inhibitor of IGFR-1,[217] which showed intermediate efficacy in RMS. Later examples include sunitinib, cediranib, and pazopanib, which are small molecules that inhibit the kinase activities of platelet-derived growth factor receptor (PDGFR) and other RTKs, VEGF receptors 1 to

3 (VEGFR1 to VEGFR3), and VEGFR1 to VEGFR3 and other RTKs, respectively.[209] Given the known resistance that emerges with RTK monotherapy, these small molecules are now being tested in conjunction with traditional chemotherapeutic agents. For example, pazopanib has been tested in combination with topotecan, and in Rh30 xenografts this combination inhibits tumorigenesis.[218] Indeed, this has supported the incorporation of pazopanib into human clinical trials (see "Clinical Research in Rhabdomyosarcoma"). Whereas the upregulation of a specific RTK in RMS warrants investigation of that RTK as a drug target, not all RTK inhibitors have efficacy. For example, although EGFR is found upregulated in some RMS tumors, erlotinib (an EGFR inhibitor) had no effect on blocking tumorigenesis in a genetically engineered mouse model of ARMS.[219]

In addition to inhibiting RTKs, whether through monoclonal antibodies or small molecules, there are also efforts to inhibit heparanases (discussed in "Metastatic Pathways in Rhabdomyosarcoma"). Pharmacologic inhibition of heparanases using SST0001, a chemically modified heparin, in RD and Rh30 xenografts showed inhibition of tumor growth. The precise mechanism is not clear, but there was evidence of decreased angiogenic factors secreted from the RMS cell lines in the in vitro studies.[220]

Inhibitors of Intracellular Signaling Pathways

Regarding downstream signaling pathways, it is clear that blockade of only one pathway is not durably antitumorigenic because of compensatory upregulation of other pathways. Therefore there are ongoing efforts to simultaneous block two or more pathways. Dual blockade of the PI3K/AKT/mTOR and RAS/MEK/ERK pathways with small molecules synergistically inhibits RMS cell growth in vivo.[221] Similarly, treatment of RMS xenografts with rapamycin was shown to block tumor growth by inhibiting not only the mTOR pathway but also Hedgehog signaling,[222] and indeed rapamycin analogues are in human clinical trials (see "Clinical Research in Rhabdomyosarcoma"). Attesting to the power of utilizing lower eukaryotes for target discovery, a screen performed in an oncogenic RAS-driven model of zebrafish RMS identified dual MEK and mTOR/S6K1 inhibition as effective.[223]

Finally, there is RAS itself, which is found mutated in a significant portion of ERMS tumors (see previous section, "Oncogene and Tumor Suppressor Gene Mutations in Rhabdomyosarcoma"). Targeting the RAS protein has proven difficult. However, silencing of Sprouty1, an upstream modulator of RAS that is also found in ERMS tumors and associated with upregulated ERK signaling, using shRNA triggers complete regression of ERMS xenograft tumors carrying a mutated oncogenic *RAS* gene,[224] suggesting that there will be alternate ways to block RAS signaling in the future.

Inhibitors of Developmental Pathways

Pharmacologic blockade of RTK signaling by small molecule inhibitors became possible because of a deep structural understanding of their enzymatic activity. As the role of the evolutionarily conserved developmental pathways (e.g., Hedgehog, Notch, Wnt, transforming growth factor-β [TGF-β]) in RMS tumorigenesis has become apparent,[225] it has become similarly imperative to understand the molecular basis for their dysregulation. For the most part, it appears that in RMS these pathways, which during normal development and tissue homeostasis direct myogenesis by promoting myogenic stem cell maintenance, expansion, and tight control of differentiation, are usurped and prevent proper myogenic lineage progression. In this regard, agents developed to inhibit members of these pathways must be evaluated for unanticipated effects on normal tissue, especially considering the continual growth and development of pediatric patients. Studies in *Ptch* mutant mice, which through increased Hedgehog signaling develop both medulloblastoma and RMS, showed that combined dosing with the epigenetic drugs 5-aza-2′-deoxycytidine and valproic acid inhibited tumor formation when treated early.[226] In human RMS xenografts, treatment with betulinic acid (a naturally occurring plant product), GANT61 (a Gli antagonist), or forskolin (also derived from a naturally occurring plant product) suppressed Hedgehog signaling and RMS tumor growth.[227-229] Recently, several additional small molecule inhibitors of Smoothened and Gli have been developed, raising the expectation that blockade of Hedgehog signaling will be possible in human cancers.[230]

Regarding Notch signaling, given its critical role in normal muscle development and the upregulation of many components of this pathway in RMS, this pathway has gained attention, and several Notch pathway genes and proteins have been suppressed using genetic (shRNA) or pharmacologic (γ-secretase inhibitors) approaches and when suppressed shown to inhibit the growth of RMS xenografts, including Notch1, Notch3, RBPJ, and Hey1.[231-233] Although as important in skeletal muscle development as Notch, the Wnt pathway is not as well understood in the pathobiology of RMS and therefore in vivo preclinical studies using genetic or pharmacologic approaches to target the Wnt pathway are lagging. Finally, regarding TGF-β signaling, this pathway, too, is under investigation in RMS. However, recently a miR that is suppressed by TGFB1 known as miR 450b-5p, when overexpressed in RMS cells inhibits cell growth in vitro and tumor xenografts in vivo and promotes myogenic differentiation.[234]

Inhibitors of Other Cellular Processes That Support Rhabdomyosarcoma Tumorigenesis

Apoptosis

In addition to specific signal transduction pathways, there are efforts to target specific cellular processes. For example, as described earlier, RMS cells can resist apoptosis (programmed cell death) through upregulation of anti-apoptotic proteins or the suppression of pro-apoptotic proteins. Therapeutic approaches therefore may include inhibiting anti-apoptotic signaling, for example through neutralizing Bcl-2 family proteins (although caution must be taken because some Bcl-2 family members have pro-survival roles), or activating pro-apoptotic signaling, for example through stimulation of the extrinsic apoptotic pathway via members of the tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) receptors.[235] Drozitumab is a monoclonal antibody to death receptor 5 that supports assembly of death-induced signaling complexes and has shown efficacy in RMS xenografts.[236] It may also be possible to reestablish normal function of mutated pro-apoptotic pathways. For example, in ARMS xenografts the MDM2 inhibitor RG7112 interferes with MDM2-TP53 binding, releasing TP53 from negative control and permitting its normal cell surveillance function.[237] Finally, although apoptosis has historically been the major focus of inducing cell death, the process of necroptosis (nonapoptotic cell death) has been found to be induced in RMS cells via obatoclax, which inhibits BCL2.[238]

Although involved not only in avoidance of apoptosis but also many other pro-tumorigenic processes, it is important to note that *MYCN* has been proven targetable through the use of antigene therapy in which a peptide nucleic acid oligonucleotide (tethered to a nuclear localization signal peptide and targeted against the antisense strand of *MYCN* exon 2) was delivered to ARMS cells. This antigene therapy caused a decrease in proliferation and an increase in apoptosis in vitro and eliminated 75% of tumors in Rh30 RMS xenografts, with 25% showing a reduction in tumor.[239]

Cell Cycle

Although apoptosis is a cellular event that can be triggered by many distinct stimuli, direct manipulation of the cell cycle and its checkpoints also provides opportunities for pharmacologic manipulation and treatment of RMS. Of long-standing interest are antimitotic agents, which interfere with transit through mitosis, including spindle assembly, chromosome positioning, and chromosome separation. Classic chemotherapy agents such as vincristine, which is a backbone of RMS therapy, interfere with the mitotic spindle by binding tubulin. Indeed, a more potent synthetic antitubulin agent, eribulin, which is distinct from the *Vinca* alkaloids in how it binds tubulin, has shown some complete responses in RMS xenografts.[240] More recently, kinases and kinesin motor proteins that control mitosis are now able to be pharmacologically targeted and agents blocking these proteins are being evaluated against human cancer panels, including RMS. The agents MLN8237 and B16727, Aurora A, and Pololike kinase inhibitors, respectively, have both demonstrated some response in RMS xenograft studies.[241,242] The kinesin spindle protein inhibitor ispinesib was toxic and ineffective in inhibiting RMS xenograft growth,[243] whereas the CENP-E kinesin inhibitor GSK923295A showed some efficacy.[244]

Regulation of Protein Stability and Turnover

The heat shock and ubiquitin-proteasome systems, which contribute to homeostasis of protein stability and turnover, have also been mined for their potential as anticancer targets. 17-DMAG, a first-in-class derivative of geldanamycin that inhibits Hsp90, showed some antitumor activity in xenograft models of ARMS,[245] whereas a non-geldanamycin Hsp90 inhibitor, AT13387, showed no objective tumor responses.[246] Bortezomib, which is approved by the U.S. Food and Drug Administration (FDA) for the treatment of several human diseases, showed activity in ERMS and ARMS xenografts in vivo.[247] MLN4924, a first-in-class NEDD8-activating enzyme inhibitor that affects the ubiquitin-proteosome pathway also showed efficacy in RMS.[248]

Epigenetic Modifiers

Currently there are two groups of agents under study that qualify as epigenetic modifiers. The first group of agents is composed of histone deacetylase (HDAC) inhibitors. Agents in the second group inhibit DNA methylation and include 5-aza-2′-deoxycytidine. Although results of early in vitro studies were promising,[249,250] there are few in vivo studies demonstrating inhibition of RMS tumorigenesis in response to epigenetic modifiers. As mentioned earlier, combined dosing with the epigenetic drugs 5-aza-2′-deoxycytidine and valproic acid, which target Dnmt and HDAC, respectively, in a genetically engineered mouse model of *Ptch*-mutant mice inhibited tumor formation, but only when the mice were treated early during tumorigenesis.[226] Additionally, drugs that target proteins involved in epigenetic regulation can have unanticipated protumorigenic effects, as in the case of the HDAC inhibitor trichostatin A and DNA demethylating agent (5-Aza), which reactivated the expression of Ezrin, a known prometastatic protein in RMS.[251]

Immunotherapy for Rhabdomyosarcoma

In addition to pharmacologic agents, there are efforts to stimulate or harness the immune system to target and kill RMS tumor cells. However, like most other cancers, RMS is remarkably successful at evading the immune system. One approach to overcome this evasion is isolation and expansion of natural killer cells obtained from normal healthy donors, which can kill human sarcoma cells in vitro and Ewing sarcoma xenografts in vivo.[252] Recently, IL-15 cytokine–induced killer cells from donors were shown to be active in xenograft models of RMS.[253] Another novel approach is chimeric antigen receptor therapy, which although still in early phases has been effective in the treatment of leukemias. Thus there is hope that this approach can be similarly used in solid tumors. To prepare for these efforts, a recent study identified candidate cell surface proteins on pediatric tumors including RMS that could be future therapeutic targets for immunotherapy.[254] Finally, there are ongoing efforts to develop vaccines to solid tumors including RMS. Given the specific expression of the PAX3-FOXO1 fusion protein in ARMS, an epitope-enhanced peptide bearing the PAX3-FOXO1 breakpoint was designed and generated. Because this peptide represents a neoantigen exclusively found in ARMS, the immune system should recognize it as such; and, indeed, dendritic cells pulsed with this peptide generated a CTL line that lysed human ARMS tumor cells in vitro.[255] Similar proposals have been made to use the fetal acetylcholine receptor and other antigens for RMS immunotherapy.[256,257]

CLINICAL RESEARCH ON RHABDOMYOSARCOMA

RMS may be the most clinically complex tumor in pediatric oncology. In addition to its histologic and biologic diversity, RMS has a remarkable variety of sites and clinical behaviors.

Much of our clinical knowledge of RMS has come from well-organized multiinstitutional clinical trials in North America and Europe. In the United States and Canada (and later Australia, New Zealand, and Switzerland) the first Intergroup Rhabdomyosarcoma Study (IRS-I) opened in 1972 and closed in 1978, recruiting patients from the pediatric division of the Southwest Oncology Group (SWOG) and the Children's Cancer Study Group (CCSG). There were five further IRS studies (II, III, IV-pilot, IV, and V), during which the pediatric division of SWOG became the Pediatric Oncology Group (POG) and the CCSG became the Children's Cancer Group (CCG). Finally, the IRS, POG, CCG, and the National Wilms Tumor Study merged to form the Children's Oncology Group (COG), and that group's Soft Tissue Sarcoma Committee completed the IRS-V studies before launching its own ARST series. Publications from the first generation of COG RMS studies (ARST series) are beginning to appear.

Meanwhile, in Europe, the International Society of Pediatric Oncology (SIOP) has conducted a series of Malignant Mesenchymal Tumor studies (SIOP 75 and MMT-84, MMT-89, and MMT-95). The German CWS *(Cooperative Weichteilsarkom Studie)* conducted four trials, CWS 81, 86, 91, and 96. The Italian Rhabdomyosarcoma Group had two clinical trials, RMS 79 and 88, before joining the CWS studies. Limited patient numbers made randomized controlled trials difficult, so the Europeans joined to form the European Paediatric Soft Tissue Sarcoma Study Group (EpSSG), which has launched a randomized controlled trial for patients with localized RMS (RMS-2005). Unfortunately, the loss of Germany for regulatory reasons has slowed accrual, and the results of many of the earlier European studies have never been published.

INCIDENCE AND EPIDEMIOLOGY

RMS accounts for about half of the soft tissue sarcomas in children and adolescents and about 3% of childhood cancer cases. This varies with age, so that they are 60% of soft tissue sarcomas in patients aged younger than 5 years and 23% in the 15- to 19-year age group.[258] They occurred in 4.6 children per million per year in 1996 to 2003 according to the Surveillance, Epidemiology and End Results (SEER) database,[259] and in the period 1973 to 2005 the incidence increased at a mean annual rate of 0.58%.[260] The highest incidence (8.4 per million children) is in the 1- to 4-year age group, after which the incidence is stable at about 4 per million children per year. SEER data show that the incidence of ERMS peaks at about age 3 and then declines until about age 10, whereas the incidence of ARMS is fairly constant from birth to age 19.[261] Most studies report a slight male preponderance (about 5:4); recent analyses of SEER data found no significant differences in incidence by race[260] or a slightly higher incidence in black children.[261]

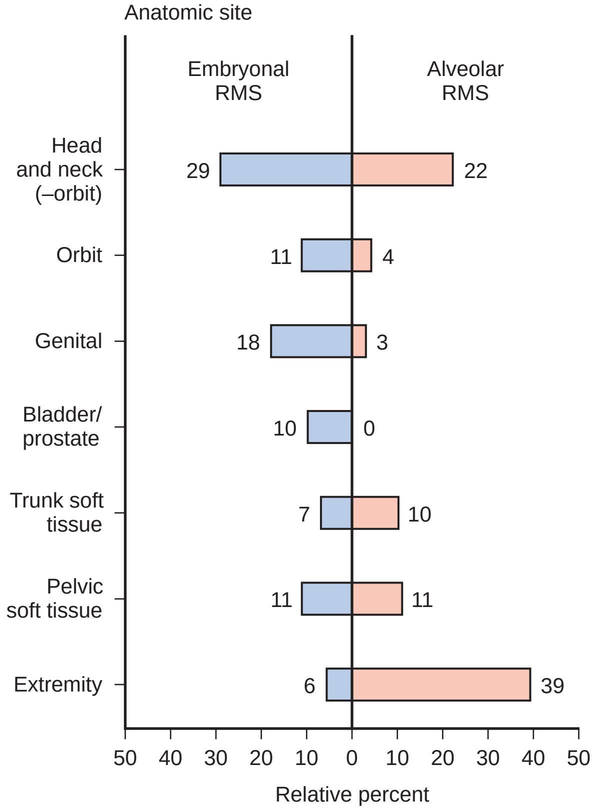

Figure 59-7 Primary sites of embryonal and alveolar RMS, percent of distribution by histology. *(From Gurney JG, Young JL, Roffers SD, et al:* Soft Tissue Sarcomas, SEER Pediatric Monograph, *Bethesda, Md., 1999, National Cancer Institute, p. 116.)*

CLINICAL PRESENTATION AND EVALUATION

RMS occurs in virtually all parts of the body outside the central nervous system (although they may involve it). ERMS often occurs in areas where there is very little skeletal muscle, such as the orbit, pharynx, sinuses, vaginal wall and paratesticular tissues. ARMS has a greater tendency to occur where there is skeletal muscle, such as in the trunk and limbs (Fig. 59-7).

The clinical presentations of either histology are myriad and vary with the primary site. For example, tumors of the parameningeal region (e.g., the sinuses and pharynx) may have cranial nerve deficits as initial symptoms, orbital tumors often produce proptosis and diplopia, and tumors of the bladder base and prostate usually cause urinary retention. Often, however, the tumor is a painless mass without associated symptoms. Usually it is hard or firm, smooth, fixed to surrounding tissues, and not tender. There may be palpable regional lymphadenopathy and, occasionally (with alveolar histology tumors), distant involved nodes and metastases to the skeleton or marrow.

The initial evaluation of a patient with a suspected RMS has three components: the evaluation of the extent and anatomic relationships of the primary tumor; the

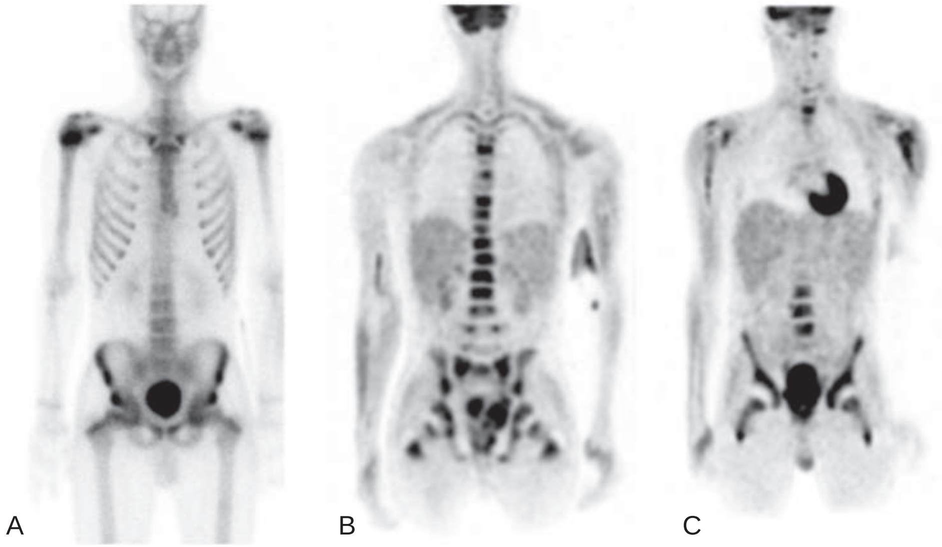

Figure 59-8 Metastatic alveolar rhabdomyosarcoma. Radionuclide bone scan (**A**) and two images from a tomographic coronal PET scan (**B** and **C**). The abnormalities in the bone scan are few and subtle; the PET scan clearly shows multiple skeletal metastases.

detection of metastases; and the identification of other problems that may be related to the tumor (e.g., a cranial nerve palsy or urinary retention) or that are unrelated but could affect therapy (e.g., a cancer predisposition syndrome).

The most appropriate time for referral to a pediatric oncology center is at the first suspicion of a malignancy. Experienced radiologists should perform the imaging of the primary tumor before a biopsy has produced local hemorrhage and edema, using equipment that can share images with computerized radiation therapy planning systems. If possible, the surgeon who will perform the definitive excision of the tumor should perform, or at least supervise, the diagnostic biopsy of a suspected sarcoma. Violation of tissue planes or neurovascular structures with inexpertly placed biopsy tracts (whether open or closed) may limit excision and reconstruction options, prevent limb salvage procedures, or increase the chances of local recurrence. Because sarcomas are often very heterogeneous and contain large areas of necrosis and because molecular techniques are increasingly important in diagnosis, generous fresh specimens are important, with frozen section confirmation of specimen adequacy before the procedure is declared complete. Many passes of the needle (10 or more) are usually required if closed techniques are used. Fine-needle aspirates do not provide the tissue architectural information currently necessary for pediatric sarcoma diagnosis or sufficient tissue for advanced diagnostic techniques.

For evaluation of the primary tumor, the current standard of care is magnetic resonance imaging (MRI) with contrast enhancement, encompassing the primary tumor and regional lymph nodes. Traditionally, patients have also undergone a spiral chest computed tomographic (CT) scan without administration of a contrast agent (although contrast enhancement is necessary to find hilar or mediastinal adenopathy or to distinguish a mass from a surrounding pleural effusion) and a radionuclide bone scan to detect skeletal metastases, as well as bilateral bone marrow aspirates and biopsies. However, a recent analysis indicates that these studies are unnecessary in patients with noninvasive tumors without regional node involvement (T1N0), which are about one third of cases.[262]

The use of fluorodeoxyglucose-18–labeled positron emission tomography (FDG-PET) is particularly promising for the detection of involved regional nodes and distant metastases[263,264] and skeletal and marrow disease not revealed by conventional techniques (Fig. 59-8). The combination of PET and CT (PET/CT) can help discern the extent of tumor versus peritumoral edema or whether a remote mass is a tumor. A retrospective study of 23 RMS patients showed that side-by-side evaluation of PET/CT and conventional imaging (primary site MRI, bone scintigraphy, marrow biopsy, chest CT) provided more accurate staging than either conventional imaging or PET/CT alone.[265] A larger single-institution study of 30 pediatric RMS patients retrospectively compared the findings of conventional imaging (MRI, chest CT, bone scintigraphy), marrow aspirates and biopsies, biopsies of selected possible metastases, and PET/CT. For regional nodes, PET/CT was equally sensitive to conventional imaging but much more specific (95% v. 14%); for bone and marrow disease PET/CT was more sensitive (detecting 4 of 4 patients with bone or marrow disease, versus 1 of 4 with bone scintigraphy); and PET/CT detected soft tissue metastases not visible on conventional imaging in 2 patients. Chest CT revealed more nodules than PET/CT (seven nodules in 6 patients vs. one nodule in 1 patient).[266] A retrospective comparison of PET/CT and conventional imaging in 35 pediatric and adult RMS patients (two thirds with alveolar histology) similarly found PET/CT more sensitive and specific for both regional node and metastatic assessment.[267] The potential role of PET/CT in assessing response to therapy will be discussed later.

Whole-body MRI for detection of metastasis was tested in several single-institution studies. In particular, a large single-institution study compared whole-body MRI, FDG-PET, and bone scintigraphy in the detection of skeletal metastases in 39 pediatric patients with a variety of tumors (including Ewing sarcoma, RMS, osteosarcoma, lymphoma, melanoma, and Langerhans cell histiocytosis), with biopsy of all detected lesions for histologic confirmation. PET had the highest sensitivity (90%), followed by whole-body MRI (82%), and bone scintigraphy (71%), although all three modalities had both false-positive and false-negative results that varied with anatomic location (for example, the high glucose uptake in the brain made PET relatively insensitive in the skull). The greatest sensitivity (96%) came from combining any two imaging modalities.[268] A recent large multicenter study enrolled a cohort of 188 children with soft tissue sarcoma, lymphoma, or neuroblastoma. With a complex system of central review, the investigators compared the findings of whole-body MRI with those of CT and disease-appropriate scintigraphy (metaiodobenzylguanidine, gallium, or [in some patients] FDG-PET). Whole-body MRI detected more skeletal metastases per patient, but this did not change the staging of any patient's tumor; and it was less sensitive than conventional imaging in detecting liver and lung metastases. The investigators concluded that whole-body MRI "is not justified" as "the initial study of choice" for staging pediatric cancers.[269]

RISK GROUP CLASSIFICATION

RMS varies tremendously in prognosis, from almost 100% survival (for orbital embryonal tumors) to virtually no prospect of survival (for disseminated alveolar tumors). There has been a variety of schemes for classifying RMS to try to match treatment intensity to prognosis. Some of the schemes are prospective, relying on tumor characteristics before any therapy, whereas others are dynamic, subject to change based on response to surgery or chemotherapy. We will consider individual prognostic variables and then the ways in which they have been combined.

Histology and Fusion Status

Patients with ARMS are less likely to survive than patients with ERMS, even if all other factors are equal. Alveolar tumors are also more likely to be regionally or metastatically disseminated at the time of diagnosis and are more likely to be invasive (Table 59-5) The difficulties in classifying tumors with alveolar histology that lack a *PAX-FOXO1* gene fusion and the differences between alveolar tumors with fusions involving *PAX3* and *PAX7* have already been discussed. So far, histology has taken precedence over fusion status, but this appears to be changing with accumulating evidence that fusion status is the key determinant of clinical behavior.[270,271]

TABLE 59-5 Clinical Features of Embryonal and Alveolar Rhabdomyosarcoma

	Embryonal Tumors	Alveolar Tumors
Age	Younger	Older
Location	Central, not muscular	Peripheral, muscular
Invasiveness	Low/moderate	High
Metastases	Lung	Everywhere
Prognoses	40% to 90% + PFS	0 to 60% PFS

PFS, Progression-free survival.

Site

The clinical behavior and prognosis of RMS varies greatly with the site of the primary tumor, independently of histology. For example, an ERMS of the orbit is almost always curable whereas an ERMS arising in the ethmoid sinus, just a few centimeters away, carries about 25% mortality despite more intense therapy. The favorable sites for RMS are the orbit, superficial head and neck, biliary tree, vagina, and paratestis; all other sites are considered unfavorable. The biologic basis for this variability remains mysterious, with many different hypotheses (size at diagnosis, access to lymphatics, ploidy, and many others) having been explored and discarded.

Age

The prognosis for patients with RMS is best in preschool and middle childhood and worse for infants, adolescents, and adults. An analysis of data from the IRS-III, IRS-IV pilot, and IRS-IV (spanning 1984 through 1997) showed that when infants younger than 1 year of age are assigned a risk of treatment failure of 1.0, the relative risk for older children is 0.4 to 0.6 and that for adolescents (≥10 years) is 0.8.[272] Although other prognostic variables such as histology, nodal status, stage, site, and clinical group differed between the three age groups, the impact of age remained when all other factors were controlled. A more recent analysis of infants enrolled in the IRS-IV and COG D9602 and D9803 studies largely confirmed these findings and noted that the outcome for infants with group III tumors (gross residual disease at the beginning of chemotherapy) have a particularly poor outcome, perhaps related to fewer than half receiving protocol-assigned radiation therapy. Overall, FFS at 5 years was 57%, 81%, and 67% for patients aged younger than 1, 1 to 9 years, and 10 years and older, respectively.[273] Prognosis varies with age gradually, however, so the 1- and 10-year boundaries are somewhat arbitrary.

Adults with RMS have a much worse prognosis than children and adolescents. The SEER registry analyzed the records of 2600 RMS patients diagnosed from 1973 to 2005. The OS rate of patients younger than age 19 was 61% at 5 years versus 27% for patients older than 19. Hazard ratios for death increased steadily with increasing age past 19 years; on multivariate analysis the other significant independent variables were histology, primary site, and extent of tumor (local, regional, metastatic).[274] A multicenter study of 169 pediatric and adult RMS diagnosed between 1977 and 2009 (ages birth to 73 years) identified through the Dutch National Histological Database System considered a variety of tumor, host, and treatment variables, many of which were significantly associated with outcome in univariate analysis. On multivariate analysis, increasing age was the most important factor influencing relapse-free survival (RFS), with histology the only other factor retaining significance.[275]

Invasiveness and Size (Tumor Stage)

Invasive tumors, those that cross tissue planes or extend beyond the organ of origin (designated T2 in the TNM system), have a worse prognosis that noninvasive tumors (T1). Similarly, patients with tumors 5 cm in diameter or larger (Tb) have a worse prognosis than those with tumors less than 5 cm (Ta). The International Rhabdomyosarcoma Workshop pooled data from four studies conducted in the late 1970s and 1980s (IRS-II, CWS-81, SIOP RMS 75, and the Italian Cooperative Group study) to examine prognostic factors in 951 patients with localized disease. In multivariate analysis, site and invasiveness were the surviving factors.[276] Histology was not among the variables considered, but it is closely related to site and invasiveness. European studies have used invasiveness for risk classification, but North American clinical trials have not, largely because a definition that would be usable in a large cooperative group has been elusive.

Size is highly correlated with invasiveness in multivariate analyses[276] and is much simpler to measure. The current COG risk classification uses stage, which depends on both site and size (Table 59-6).

Clinical Group

The extent of tumor when chemotherapy begins determines the clinical group (see Table 59-6). It is not a true staging system, because it depends on the initial surgery; stage and group only overlap in patients with metastases (stage 4, group IV). IRS-I showed clinical group to be a powerful prognostic variable, but it is a complex one: site, invasiveness, the aggressiveness of the surgeon, the attitude of the family toward mutilating surgery, and the confidence of the treating team in chemotherapy and radiation therapy can all influence whether a tumor is excised with negative margins at diagnosis (group I) or only sampled (group III).

TABLE 59-6 Comparison of IRS Clinical Group and Stage for Rhabdomyosarcoma

GROUP I: Complete excision No gross or microscopic residual disease	STAGE 1: Favorable site Orbit, superficial head and neck, biliary tree, paratestes, vagina
GROUP II: Microscopic residual disease IIa: Microscopically positive excision margins IIb: Excision margins negative; involved nodes but completely excised; most distant node negative IIc: Microscopically positive margins at primary site or grossly excised nodes; or most distant node positive	STAGE 2: Unfavorable site, diameter ≤5 cm, and nodes clinically negative or unknown All sites except the favorable ones above are unfavorable.
GROUP III: Gross residual disease Biopsy only or incomplete excision	STAGE 3: Unfavorable site and diameter >5 cm or clinically involved nodes
GROUP IV: Distant metastases	STAGE 4: Distant metastases

Lymph Node Involvement

Lymph node positivity is variably defined as clinical involvement on physical examination or imaging or histologic involvement at biopsy; some reports provide no definition. The International Rhabdomyosarcoma Workshop found lymph node involvement (undefined) to be a prognostic factor in univariate analysis but not as strong as tumor stage, size, or site.[276] Clinical involvement of local or regional lymph nodes was prognostically significant among IRS-III and IRS-IV patients with stage 3, group III ARMS (5-year OS of 66% with negative nodes vs. 34% for positive nodes, $P = .01$), but not for patients with embryonal tumors.[277] A later study using IRS-IV cases with localized tumors or single metastatic sites came to the same conclusion about ERMS, but for ARMS multivariate analysis showed nodal positivity (whether by physical examination, imaging, or histology) to be a potent adverse factor, with N0 and N1 5-year FFS rates of 73% and 43%, respectively.[278] The investigators also found that 80% of N1 primary ARMS overexpressed immune-related genes such as β_2-microglobulin, immunoglobulins, complement, and histocompatibility complex components.

Metastases at Diagnosis

Patients with metastases at diagnosis fare poorly, and there has been little change over the years. Patients with group IV tumors had a 5-year OS of 20% in IRS-I, 23% in IRS-II, 20% in CWS-86, and 23% in MMT-98 and across a range of IRS studies beginning with IRS-III.[279-283] However, they are not a uniform population. Patients younger than the age of 10 years with metastatic ERMS were classified as intermediate-risk (rather than high-risk) patients in the IRS-V series of studies because of a 51% FFS rate in the previous three studies.[272,284] An analysis of patients with metastases at diagnosis in IRS-IV found that the number of metastatic sites and histology defined two risk groups: patients with one or two metastatic sites, or three metastatic sites with embryonal histology, had a 3-year OS of 43% to 47%, but patients with three or more metastatic sites and alveolar histology had a 3-year survival of only 5%.[285] After pooling 788 patients with metastatic RMS from nine cooperative group studies (IRS, SIOP MMT, and Italian), a multivariate analysis identified four unfavorable prognostic factors: unfavorable site, bone or marrow metastases, age younger than 1 or older than 9 years, and three or more metastatic sites. Applying these factors divided the population into two groups: the first had none to one unfavorable factor, accounted for 42% of the patients, and had an event-free survival (EFS) of 44%; the second had two or more factors, accounted for 58% of the patients, and had an EFS of 14%.[286]

Interactions

All of these variables interact, which complicates classification. For example, large extremity primary tumors are usually alveolar histology, often have involved regional nodes, and often occur in teenagers, and ARMS are usually invasive.

A recent multivariate analysis of 1164 CWS study patients, enrolled between 1980 and 2002, identified histology, age (≤10 years vs. >10 years), tumor size (5-cm cutoff), clinical group, site, and the use of radiation therapy in treatment as significant factors. Further distillation led to three groups of patients, those with (1) embryonal tumors 5 cm or less, whose 5-year EFS was 76%, whose relapses were only 19% systemic, and whose postrelapse survival was 46%; (2) embryonal tumors larger than 5 cm, with an EFS of 64%, whose relapses were 32% systemic, and postrelapse survival was 18%; and (3) alveolar tumors, with an EFS of 46%, systemic relapse rate of 52%, and postrelapse survival of 13%.[287]

Many different risk classification schemes exist for RMS, and they change from one clinical trial to another. In the system used by the COG for current studies, stage (which depends on site and size), clinical group, and histology are combined to produce a three-way risk classification (Fig. 59-9 and Table 59-7) . The system used in the current European studies assigns patients to four risk groups (low, standard, high, and very high) based on histology, clinical group (referred to as stage), site, nodal involvement, tumor size, and age; these four risk groups are then divided into eight subgroups based on clinical group, nodal status, age, and tumor size (Table 59-8). In view of recent information on the overarching importance of *PAX-FOXO1* fusion status,[271] risk classifications are likely to change in the next generation of cooperative group studies.

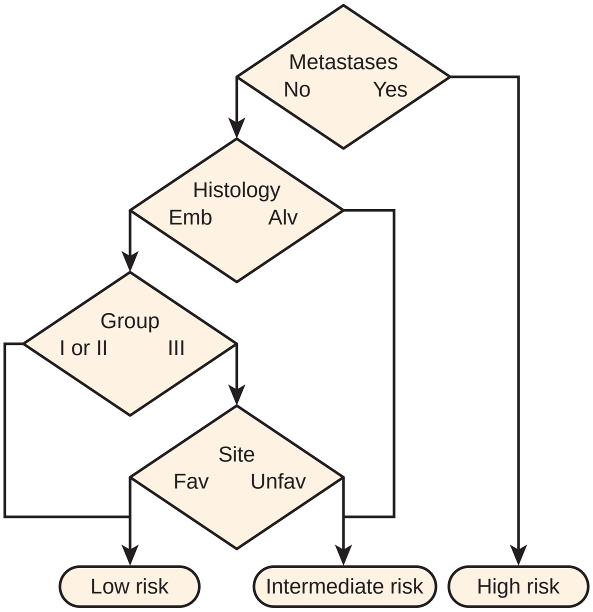

Figure 59-9 Risk group assignment algorithm for the first generation of Children's Oncology Group ARST studies (ARST0331, ARST0431, ARST0531). The results of those studies and the use of molecular rather than histologic criteria for alveolar RMS are likely to change this considerably. *Alv,* Alveolar; *Emb,* embryonal.

TABLE 59-7 Children's Oncology Group Risk Stratification for Rhabdomyosarcoma

	Low Risk	Intermediate Risk	High Risk
Metastases	No	No	Yes
Histology	Embryonal	Any	Any
Stage	Any if group I or II; 1 if group III	1, 2, or 3 if alveolar histology; 2 or 3 if embryonal histology	4
Group	I, II, or III if stage 1; I or II if stage 2 or 3	III if stage 2 or 3; I, II, or III if alveolar histology	IV

TREATMENT

Before the advent of chemotherapy for RMS, survival was rare—a retrospective review of 64 CCSG RMS cases with "complete" surgical excisions revealed a survival rate of less than 8%.[288] The dramatic progress in treatment and survival of RMS patients over the past 40 years has flowed mostly from multidisciplinary care, in which surgeons, oncologists, radiologists, radiation oncologists, and pathologists approach treatment in a planned, coordinated fashion. Such care, which was pioneered in the late 1960s,[289] has been the foundation for clinical trials in RMS in the United States and Europe.

Chemotherapy

Systemic chemotherapy for all patients with RMS began with a Children's Cancer Study Group randomized controlled trial, which ran from 1967 to 1971. Patients with complete excisions (group I) were randomly assigned to chemotherapy with vincristine and dactinomycin (actinomycin D) for 6 to 13 nine-week cycles or to observation only, whereas patients with microscopic residual disease were nonrandomly assigned to the chemotherapy arm of the trial. RFS at 4 years was 82% in the chemotherapy group and 47% in the control group ($P = .03$); RFS was 90% in group II.[288] This trial established the role of chemotherapy in treating RMS and also established the feasibility and importance of coordinated multidisciplinary care on a national, multiinstitutional scale.

Cyclophosphamide

Cyclophosphamide was part of combination chemotherapy for RMS from some of the earliest trials, based on its efficacy as a single agent in patients with advanced RMS.[289,290] The vincristine-dactinomycin (actinomycin D)-cyclophosphamide (VAC) combination has been in continuous use since IRS-I[280] and the first European

TABLE 59-8 European Paediatric Soft Tissue Sarcoma Study Group Risk Stratification for Rhabdomyosarcoma

Risk Group	Subgroups	Pathology	Postsurgical Stage (IRS Group)	Site	Node Stage	Size and Age
Low risk	A	Favorable	I	Any	N0	Favorable
Standard risk	B	Favorable	I	Any	N0	Unfavorable
	C	Favorable	II, III	Favorable	N0	Any
	D	Favorable	II, III	Unfavorable	N0	Favorable
High risk	E	Favorable	II, III	Unfavorable	N0	Unfavorable
	F	Favorable	II, III	Any	N1	Any
	G	Unfavorable	I, II, III	Any	N0	Any
Very high risk	H	Unfavorable	I, II, III	Any	N	Any

cooperative group trials. The standard North American chemotherapy combination for patients with intermediate-risk tumors is still the VAC regimen. The exact composition of the VAC regimen has varied considerably over time (Table 59-9), but no randomized controlled trial has shown any combination to be more effective.

In IRS-I, patients with group II tumors were randomized between 2-year regimens consisting of vincristine-dactinomycin (VA) (with six doses of vincristine and 5 consecutive days of dactinomycin per 9-week cycle) or VAC (12 weekly doses of vincristine at the start of therapy only, dactinomycin every 12 weeks, and daily oral cyclophosphamide). There was no significant difference between the two study arms,[280] but the design of the comparison allows one to conclude only that cyclophosphamide could substitute for 60 doses of vincristine and three cycles of dactinomycin.

The IRS-II study addressed the role of cyclophosphamide in two randomizations. In group I patients, the VAC regimen from IRS-I (for 2 years) was compared with the VA regimen alone for 1 year, with the same 12 initial weekly doses of vincristine and dactinomycin every 12 weeks. The VAC regimen provided a statistically insignificant advantage in disease-free survival (DFS) but no advantage in OS. For group II patients there was a randomization between two 1-year regimens: the VA regimen with 9-week cycles incorporating six weekly doses of vincristine and one 5-day series of dactinomycin doses per cycle and a VAC modification with 4-week cycles each containing a single dose of vincristine, a single 5-day series of dactinomycin injections, and intravenous cyclophosphamide. The contest was a draw,[281] and because the VA regimen had three times the vincristine and half the dactinomycin of the cyclophosphamide-containing regimen, inferences regarding the role of cyclophosphamide are impossible.[291] There is evidence that cyclophosphamide (or ifosfamide) can allow omission of radiation therapy for some patients with vaginal RMS, however (discussed later).

There is also no evidence of a relationship between the dose of cyclophosphamide and its efficacy. For intermediate-risk patients getting the VAC regimen, IRS-III prescribed the equivalent of 900 mg/m^2 per 3-week cycle in regimen 34[292]; IRS-IV used 2.2 g/m^2 per cycle in its VAC regimen[293]; and a pilot IRS study tried 3.6 g/m^2 of cyclophosphamide per cycle (a dose of 4.5 g/m^2 proved too toxic).[294] However, there was no change in FFS rates across these three trials despite a fourfold increase in cyclophosphamide dose and dose intensity,[293,294] and the most recent COG ARST studies use 1200 mg/m^2 of cyclophosphamide in their VAC arms.

Doxorubicin

Doxorubicin is probably the single most effective agent against sarcomas generally, but its role in RMS remains been both unclear and controversial despite three decades of study. Concern about its cardiotoxicity (especially in young patients) has limited its use. The value of doxorubicin in treating RMS, and particularly its relative efficacy against embryonal and alveolar tumors, remain open questions.

The investigators of the IRS tried doxorubicin in a variety of ways. In IRS-I, patients with group III and IV tumors were randomized between VAC (with dactinomycin every 12 weeks and continuous oral cyclophosphamide) and the same regimen with doxorubicin doses halfway between the dactinomycin cycles. The addition of doxorubicin made no difference to either DFS or OS.[280] The IRS-II study treated group III and IV patients with more modern, every-4-week intravenous regimens, randomizing between VAC and a regimen in which doxorubicin replaced dactinomycin in alternate cycles. Again, there were no significant differences in DFS or OS, although the results were much better than those of IRS-I.[281] Unfortunately there was no analysis to see whether doxorubicin might have affected ERMS or ARMS patients differently.[291]

IRS-III used doxorubicin in two randomizations. For group II patients with favorable (embryonal) histology, vincristine-dactinomycin-doxorubicin was superior to VA alone (89% vs. 54% 5-year survival, $P = .03$); however, patients in the VA arm of the study had worse results than those in IRS-II, and when the IRS-II and III results were combined the statistical significance disappeared (89% vs. 73% for survival, $P = .14$).[292] Doxorubicin was also part of all three randomized regimens for clinical group III and IV patients in complex ways that make its contribution to the results impossible to assess.[291]

The COG compared six "phase II window" regimens to IRS-III in 420 patients with group IV (metastatic)

TABLE 59-9 Evolution of Vincristine/Dactinomycin (Actinomycin D)/Cyclophosphamide (VAC) Chemotherapy

	VCR Dose	VCR Schedule	AMD Dose	AMD Schedule[†]	CPM Dose	CPM Schedule	Duration	Total VCR	Total AMD	Total CPM
IRS-I	2 mg/m^2; max: 2 mg	Weekly × 12	0.015 mg/kg/day × 5 days; max: 0.5 mg/dose	q12 wk	2.5 mg/kg	Daily PO	2 yr	12 doses	10 cycles	51.5 g/m^2
IRS-II*	2 mg/m^2; max: 2 mg	Weekly × 12, then q4 wk	0.015 mg/kg/day × 5 days; max: 0.5 mg/dose	q4 wk	10 mg/kg/day × 3	× 1, q3-4 wk	1 yr for group II, 2 yr for others	35 doses	24 cycles	27 doses, 24.3 g/m^2
IRS-III	1.5 mg/m^2; max: 2 mg	Weekly × 12, then q3-4 wk	0.015 mg/kg/day × 5 days; max: 0.5 mg/dose	q3-4 wk	10 mg/kg/day × 3	× 1, q3-4 wk	2 yr	36 doses	21 cycles	27 doses, 24.3 g/m^2
IRS-IVP	1.5 mg/m^2; max: 2 mg	Weekly × 12, then q3 wk with q1 wk intervals	1.35 mg/m^2 (1 dose)	q3 wk	3600 to 4500 mg/m^2 (first four cycles), then 2200 mg/m^2 IV	× 1, q3 wk	38 wk	32 doses	11 doses	13 doses, 34.2 to 37.8 g/m^2
IRS-IV	1.5 mg/m^2; max: 2 mg	Weekly × 12, then q3 wk with q1 wk intervals	0.015 mg/kg/day × 5 days; max: 0.5 mg/dose	q3 wk	2200 mg/m^2 IV	× 1, q3 wk	44 wk	32 doses	9 cycles	12 doses, 26.4 g/m^2
IRS-V	1.5 mg/m^2; max: 2 mg	Weekly × 12, then q3 wk with q1 wk intervals	1.5 mg/m^2; max: 2 mg	q3 wk	2200 mg/m^2 IV	× 1, q3 wk	40 wk	30 doses	12 doses	14 doses, 30.8 g/m^2
COG ARST[‡]	1.5 mg/m^2; max: 2 mg	Weekly × 12, then q3 wk with q1 wk intervals	0.045 mg/kg (max 2.5 mg)[‡]	q3 wk	1200 mg/m^2 IV	× 1, q3 wk	40 wk	30 doses	12 doses	14 doses, 16.8 g/m^2

AMD, Actinomycin (dactinomycin); *ARST*, Rhabdomyosarcoma and Soft Tissue; *CPM*, cyclophosphamide; *IV*, intravenously; *PO*, orally; *VCR*, vincristine.

*Repetitive-pulse VAC.

[†] Except during radiation therapy.

[‡] Lower doses for infants.

RMS. Patients receiving the doxorubicin-ifosfamide and ifosfamide-etoposide combinations and the IRS-III treatment did best in terms of FFS; there was no ultimate difference in OS, however.[279] Again, this analysis failed to shed any specific light on the role of doxorubicin.

In Europe, doxorubicin was part of the vincristine-doxorubicin (Adriamycin)-cyclophosphamide/dactinomycin (actinomycin D) (VACA) and vincristine-doxorubicin (Adriamycin)-ifosfamide-dactinomycin (actinomycin D) (VAIA) regimens of CWS-81 and CWS-86, respectively, was part of retrieval regimens for poor responders in MMT-84, and was widely used in the Italian RMS 79 and RMS 88 studies, but there were no randomized comparisons.[282,295] The addition of epirubicin (a doxorubicin analogue) along with carboplatin and etoposide proved to be no improvement over ifosfamide-vincristine-dactinomycin (actinomycin D) (IVA) in EFS or OS in the MMT-95 study of patients with incompletely excised RMS of unfavorable sites; and the six-drug regimen was considerably more toxic.[296] We still do not know the value of doxorubicin (or other anthracyclines) in treating RMS.

Ifosfamide

DeKraker and Voute reported promising phase II results for the combination of vincristine and ifosfamide and went on to substitute ifosfamide for cyclophosphamide in the VAC combination in an study of 18 previously untreated patients.[297] The German CWS-86 study substituted ifosfamide for cyclophosphamide to change its VACA combination to VAIA, and the results were slightly improved[282]; however, it was not a randomized controlled trial. A randomized controlled comparison of cyclophosphamide and ifosfamide had to await IRS-IV; 457 patients were randomly assigned to either VAC (with cyclophosphamide as a single 2.2 g/m^2 dose) or VAI (with ifosfamide as five daily doses of 1.8 g/m^2 each); the Kaplan-Meier plots of FFS were identical.[293] Thus, although the IVA regimen has long been the European standard for intermediate-risk RMS, there are no data demonstrating its superiority to VAC; and ifosfamide has more urothelial, renal, and neurologic toxicity than cyclophosphamide.[298,299]

Etoposide

A phase II study of etoposide showed some activity in RMS.[300] The IRS-III had a three-way randomization for intermediate-risk patients that included a comparison of VAC with VAC plus cisplatin, plus or minus etoposide. Neither the cisplatin nor the cisplatin-etoposide combination added to the efficacy of VAC.[292]

In a comparison of “phase II window” regimens for patients with metastatic disease at diagnosis, in contrast, ifosfamide-etoposide was significantly superior to the IRS-III combination therapy, ifosfamide-doxorubicin, irinotecan, vincristine-melphalan, topotecan, or topotecan-cyclophosphamide in producing FFS. Survival of the ifosfamide-etoposide–treated patients was also longer, although the proportion surviving at 5 years was not improved.[279]

The combination of ifosfamide and etoposide produced complete or partial responses in 9 of 13 patients with recurrent or refractory RMS in a phase II National Cancer Institute study,[301] a remarkable level of activity. In the IRS-IV study, intermediate-risk patients were randomly assigned to chemotherapy with vincristine-ifosfamide-etoposide, VAC, or VAI; the three regimens had almost identical efficacy.[293] This showed that not only cyclophosphamide and ifosfamide are interchangeable (as given in the trial) but so are etoposide and dactinomycin. Because dactinomycin can be given in a single dose rather than three to five daily doses, and because all four patients who developed myeloid leukemia or myelodysplasia as a second malignancy in IRS-IV had received etoposide,[293] VAC was carried forward as the control regimen for the IRS-V study.

Oral etoposide as a single agent, given daily for 21 days in every 28-day cycle, produced stable disease after two cycles in 3 of 11 patients with refractory or relapsed RMS or other soft tissue sarcoma in a British phase II trial.[302] Responses to oral etoposide appeared to be independent of previous etoposide exposure. A Turkish phase II study of a similar regimen included 4 patients with RMS; 1 had a durable complete response (87+ months), and another had a partial response lasting 10 months.[303] There have been no reports of regimens incorporating oral etoposide into initial therapy or any combination regimens using it in RMS or other pediatric sarcomas.

Topotecan

Topotecan is a camptothecin analogue and as such is a topoisomerase I poison that appeared to be active against a variety of pediatric solid tumors in preclinical trials. In a phase II Pediatric Oncology Group study, the topotecan-cyclophosphamide combination produced complete or partial responses in 10 of 15 patients with RMS.[304] The IRS-COG conducted a “phase II window” study of topotecan alone,[305] and then topotecan with cyclophosphamide,[306] in patients with group IV (metastatic at diagnosis) RMS, but neither distinguished itself in either EFS or OS.[279] More patients with alveolar histology responded to topotecan alone,[305] but the ERMS and ARMS patients responded similarly to topotecan-cyclophosphamide.[304,306]

The IRS-V intermediate-risk study randomized 516 patients between VAC and VAC alternating with vincristine-topotecan-cyclophosphamide. There were no differences in EFS or OS between the two regimens and no differences in toxicity apart from a slightly higher incidence of febrile neutropenia in the VAC arm of the study.[307]

Irinotecan

Irinotecan is another topoisomerase I poison with promising preclinical activity against pediatric solid tumors in preclinical models.[308] A British-French phase II study of irinotecan given as a single bolus dose every 3 weeks to patients with relapsed RMS produced only one complete response and three partial responses among 35 patients.[309] The results of a COG phase II study were similar, with one partial response among 18 RMS patients using a “daily times five” schedule (5 consecutive days of treatment every 3 weeks).[310] A “daily times five times two” schedule (5 days of treatment, 2 days off, then 5 more days of treatment, repeated every 3 weeks) was shown to be promising in both a xenograft model and children with refractory solid tumors in a phase I study,[311] but in an Italian phase II study only 2 of 12 RMS patients had a complete or partial response.[312]

Vincristine and topotecan appeared to be synergistic in mouse xenografts,[313] inspiring a combination of vincristine and irinotecan in an IRS (later COG) study.[314] In the first part of the study, which enrolled patients with RMS metastatic at diagnosis, patients received 6 weeks (two cycles) of irinotecan using the "daily × 5 × 2" schedule, followed by VAC; in the second part patients were treated with vincristine-irinotecan. The response rate for the irinotecan window was 42%, but 32% had progressive disease; and the response rate to the combination vincristine-irinotecan window was 70%, with only 8% having progressive disease. Initial responses did not translate into improved survival, however: patients who declined "phase II window" therapy received VAC alone and had a similar response rate and FFS (23%) to patients receiving vincristine-irinotecan.

A subsequent COG study randomized patients with relapsed or refractory RMS between the "daily × 5 × 2" schedule (10 doses over 2 weeks) and a "daily × 5 × 1" schedule (five doses in 1 week) and found no significant differences in response or toxicity; the authors recommended carrying the more-convenient shorter regimen forward.[315] The most recent COG study for patients with intermediate-risk RMS randomized patients between VAC and alternating 6-week blocks of vincristine-irinotecan and VAC; results are anticipated soon.

Other Agents

Despite good results when the cisplatin-etoposide combination was tested in a phase II study,[316] cisplatin was shown not to add to the efficacy of VAC in intermediate-risk patients in IRS-III, either alone or in combination with etoposide (see earlier). There has been no evaluation of carboplatin in a phase III study, but the addition of carboplatin to the ifosfamide-etoposide combination (the ICE regimen) in a phase II study produced 51% complete and partial responses in patients with a variety of relapsed sarcomas,[317] which was very similar to the response rate to ifosfamide-etoposide, and with greater toxicity. The SIOP MMT-98 study included a "phase II window" of carboplatin in 16 RMS patients with metastases at diagnosis. Five patients had complete or partial responses after two cycles (31%), but 4 (25%) had progressive disease,[318] and the carboplatin-treated patients had significantly worse 3-year EFS than those treated with doxorubicin "window" therapy or those treated with standard four-drug initial therapy.[283] These results, along with the prolonged myelosuppression it produces, have limited enthusiasm for carboplatin.

Melphalan with vincristine was a "phase II window" combination in an IRS-IV trial for patients with metastases at diagnosis; however, it produced an unimpressive response rate and more toxicity than ifosfamide/etoposide.[279,319]

Combinations

Two attempts to improve outcome for patients with intermediate- or high-risk RMS with intense combinations of several agents have failed in randomized controlled trials. IRS-III compared VAC with the same drugs plus doxorubicin and cisplatin, etoposide, or both; the outcomes were identical for the three arms of the study.[292] The MMT-95 study randomly assigned similar patients to IVA or IVA plus carboplatin, epirubicin, and etoposide; the EFS and OS were the same at 3, 5, and 10 years, although the toxicity of the intensified regimen was significantly greater and it was associated with twice as many second malignancies.[296]

The success of alternating vincristine-doxorubicin-cyclophosphamide and ifosfamide-etoposide (VDC-IE) in Ewing sarcoma inspired a limited-institution trial of that therapy in 46 patients with intermediate-risk RMS and a comparison with the results with similar patients in IRS-IV. FFS for VDC-IE and IRS-IV were 82% and 72%, respectively (P = .26), and OS at 5 years was 76% for both. However, a comparison of the VDC-IE patients in a stratified analysis with 346 IRS-IV patients matched for site, histology, age, and clinical group showed a relative risk of failure of 0.5 with VDC-IE (P = .06).[320] The COG has completed a study of interval-compressed VDC-IE combined with vincristine and irinotecan in patients with metastatic RMS (ARST0431), but the results are not yet available.

Alternating topotecan-cyclophosphamide with VAC did not improve outcomes in patients with intermediate-risk RMS in the COG D9803 study[307]; and the results of the ARST0531 study comparing VAC with VAC alternating with vincristine-irinotecan are awaited.

A French phase II study of vinorelbine and continuous oral cyclophosphamide in relapsed pediatric soft tissue sarcomas showed an overall response rate of 36% among 50 patients with RMS.[321] This combination is under study in a phase III EpSSG study (see later).

Duration of Chemotherapy

The IRS-I, II, and III studies prescribed 2 years of treatment for most patients; in IRS-IV the duration of treatment was trimmed to 44 weeks for patients with intermediate-risk tumors and 32 weeks for patients with low-risk tumors.[293] In contrast, the European MMT-84 and CWS-81 and CWS-86 studies used 30 to 56 weeks of therapy.[282,322] The recent COG trials used only 22 weeks of therapy for patients with the lowest-risk tumors and 42 and 51 weeks for intermediate- and high-risk patients respectively. Although there have been no apparent adverse consequences of shorter durations of therapy, there have been no systematic controlled comparisons.

The current EpSSG study is testing the efficacy of 24 weeks of "maintenance" therapy with vinorelbine and oral cyclophosphamide after 26 weeks of intense cyclic chemotherapy for high-risk patients who achieve a complete response.

Treatment Strategies

There have been three broad approaches to the treatment of RMS: the SIOP MMT studies have used intense initial chemotherapy and then SIOP tried to tailor primary tumor treatment according to responses to initial chemotherapy, so as to minimize the use of surgery and radiation (with their accompanying late effects). The Intergroup Rhabdomyosarcoma Studies in North America (now the Soft Tissue Tumor Committee of the COG) has sought to maximize EFS through the use of chemotherapy, surgery, and radiation therapy in almost all patients. The German-Italian CWS studies have taken an intermediate approach. The European groups established a joint European Paediatric Soft Tissue Sarcoma Study Group (EpSSG), which has launched a protocol for localized RMS (RMS-2005), although the Germans have withdrawn from the consortium.

These different philosophies are illustrated in the groups' treatments for orbital RMS. The MMT-84 and MMT-89 studies treated patients with intense multiagent chemotherapy and no radiation therapy for those achieving a complete response. The IRS gave all patients radiation therapy (45 to 55 Gy, depending on the study) and evolving chemotherapy that was either relatively mild (vincristine and dactinomycin) or intense (the IRS-IV randomization between VAC, VIE, and IVA). The CWS studies modulated the radiation dose according to the response to intense multiagent chemotherapy: 40 or 50 Gy in CWS-81 and the Italian ICG-88 study and 32 or 54.4 Gy in CWS-86 for good and poor responders, respectively. Although the three approaches led to very different EFS rates at 10 years (57% for MMT to 86% for IRS, $P < .001$), the OS rates were almost identical (85% and 88%, $P = .67$). The incidence of radiation-associated late effects was higher in the IRS patients than in the MMT patients, although the total burden of therapy in the MMT approach includes the treatment of relapse in 37% of patients.[323]

A recent comparison of Intergroup Rhabdomyosarcoma Study Group (IRSG), SIOP MMT, Italian ICG, and German CWS approaches to bladder-prostate RMS reflected similarly divergent treatment philosophies. Forty-eight percent of SIOP-ICG patients received radiation as part of their initial therapy, compared with 85% of IRSG-CWS patients. However, there were no significant differences in FFS and OS between the groups.[324]

A comparison of RMS of all sites treated on MMT-89 and IRS-IV gave a considerable advantage to the IRS approach, however. Overall, IRS-IV had higher EFS and OS than MMT-89 (78% vs. 57% and 84% vs. 71%, respectively). For some sites there was no difference (e.g., genitourinary tract, not including bladder and prostate: IRS-IV vs. MMT-89 83% vs. 82% EFS, 90% vs. 94% OS), but for others the difference was large (e.g., limbs, IRS-IV vs. MMT-89 64% vs. 35% EFS, 71% vs. 46% OS). For patients with ERMS, the IRS approach had a small advantage for OS (87% vs. 78%) but a large advantage for patients with ARMS (71% vs. 38%), orbital tumors (100% vs. 85%), and nonparameningeal head and neck tumors (89% vs. 64%).[325] Another review found that the four major RMS clinical trial groups enjoyed roughly equal success in preventing metastatic relapse, but there were considerable differences in local relapse, ranging from 13% for the IRS to 30% for the MMT; the CWS and Italian groups were in the middle, with 19% and 22%.[287]

Response Assessment

Recent results call into question the CWS strategy of modifying treatment according to primary tumor response assessed by conventional imaging (CT or MRI). A review of group III patients treated on IRS-IV demonstrated no relationship between response to the first 8 weeks of therapy (complete, partial, or none) and 5-year FFS. This was true for patients who were initially treated with chemotherapy alone, as well as for those with parameningeal tumors with intracranial extension who received early radiation therapy. The only statistically significant difference found was among patients with ARMS, in whom patients with no response had better FFS (81%) than patients with complete (71%) or partial (39%) responses ($P = .04$).[264] More recently, a review of imaging and second-look surgery results from IRS-IV patients with group III tumors showed a weak relationship between imaging response and histologic response at second-look surgery, with tumor viability at second-look surgery associated with better FFS.[326]

FDG-PET imaging might prove to be useful, because it can differentiate between viable tumor and a residual mass of necrosis or fibrosis.[327] A single-institution retrospective study reviewed RMS patients who had PET/CT performed at diagnosis, after initial chemotherapy, and after radiation therapy. For the 68 patients who had scans at all three times, PET negativity after initial chemotherapy was weakly associated with better local RFS (97% vs. 81% at 3 years, $P = .06$), although the association was stronger for postirradiation PET negativity (94% vs. 75%, $P = .02$). Among patients with a complete response by CT, PET response predicted better local RFS (97% vs. 43%, $P = .01$); but among patients with a residual mass on CT, PET response was not useful (3-year local RFS 80% vs. 64%, $P = .72$).[328]

Current Practice and Protocols

Most RMS patients in North America are enrolled on COG studies, when they are open for accrual. Patients are classified as of low, intermediate, or high risk based on whether there are metastases, the tumor stage, histology, and clinical group (see Table 59-7). Low-risk patients were treated with four cycles of VAC (using a single 1200-mg/m^2 dose of cyclophosphamide), followed by vincristine-dactinomycin for a total of 6 months or 1 year of chemotherapy. Patients with group II or III tumors receive radiation therapy. Intermediate-risk patients were randomized on the COG ARST-0531 study between the standard therapy of VAC for 1 year, or a regimen in which blocks of vincristine-irinotecan therapy alternate with blocks of VAC; results are pending. The results of treatment in high-risk patients are poor enough that it is difficult to designate any treatment as "standard"; the COG recently completed a single-arm study using vincristine-irinotecan and interval-compressed (every-2-week) vincristine-doxorubicin-cyclophosphamide alternating with ifosfamide and etoposide, but the data are not yet available.

The EpSSG is using a complex algorithm to classify patients without metastases into eight risk groups and subgroups, with further treatment subdivisions based on response to initial chemotherapy (see Table 59-8). Low-risk patients are being treated with eight cycles of vincristine-dactinomycin. Standard-risk patients are receiving regimens including IVA and vincristine-dactinomycin, whereas high-risk patients are being enrolled in two randomized controlled trials, one evaluating the role of doxorubicin added to IVA and the other exploring "maintenance" chemotherapy with vinorelbine and cyclophosphamide. "Very high risk" patients (those with alveolar histology and involved nodes; EpSSG excludes patients with metastases) are being treated with IVA, doxorubicin, and maintenance vinorelbine-cyclophosphamide. All patients except those with group I ERMS are also receiving radiation therapy.

Primary Tumor Treatment

When only local therapy with surgery and irradiation was available, the survival rate of RMS patients was dismal. Chemotherapy has dramatically improved survival, and it has also changed the surgical and radiotherapeutic approaches, with minimization of late effects becoming a new priority. Optimal outcomes require multidisciplinary care.

Surgery

The surgeon is often involved with an RMS patient from the time of initial biopsy. This is best done at the cancer center where treatment will occur and where a full complement of diagnostic tools (including molecular techniques) is available. The biopsy needs careful planning and execution, because diagnosis, treatment, and late effects can all depend on it.

The earliest classification system for RMS, the IRS clinical grouping system, is based on the amount of tumor remaining after the first surgical intervention, be it a complete excision with clear margins (group I) or only a biopsy with gross residual disease remaining (group III) (see Table 59-5). IRS-I showed that the clinical group is a powerful predictor of survival[280] and established the role of surgery in the treatment of RMS in the chemotherapy era. Although initial complete surgical excision can involve disfigurement or loss of function, it may have a smaller late effects burden than primary tumor treatment with radiation in some patients, so multidisciplinary consultation is essential.

When a patient's initial excision leaves microscopically positive margins (group II), or when the initial excision was performed outside the pediatric cancer center, there may be value in a "primary reexcision" before chemotherapy begins. An analysis of patients with trunk or limb RMS in IRS-I and IRS-II showed that group II patients converted to group I had the same survival as patients who were rendered group I in their initial procedure. Patients who were referred as group I patients and had primary reexcisions had superior outcomes to those who did not.[329]

Regional lymph node sampling is important in limb primary tumors, which often have alveolar histology and a predilection for nodal involvement. Patients age 10 years or older with paratesticular RMS also have an increased risk of paraspinal nodal relapse and should have node sampling. Otherwise, lymph node sampling may be limited to nodes that are suspicious by physical examination or imaging.[330,331]

Traditional surgical teaching is that an attempt at excision is not valuable unless the patient can be left with microscopic residual disease at most (group I or II). Among patients with unresectable tumors (group III), debulking surgery may be beneficial even if the patients remain in clinical group III. In a retrospective study of IRS patients treated between 1984 and 1991 with large (≥5 cm) group III or IV retroperitoneal tumors, patients with embryonal histology who underwent debulking surgery before chemotherapy fared better than those who did not (FFS 72% vs. 39% at 4 years, $P = .03$); too few patients with alveolar histology tumors had debulking surgery to permit analysis.[332] It is not yet clear whether this principle applies only to retroperitoneal tumors or whether it is generally applicable. However, a retrospective analysis of the Italian RMS-79, RMS-88, and RMS-96 protocols that compared the fate of 323 patients with biopsy only and 71 patients with debulking surgery (defined as more than 50% excision but still group III) found no overall benefit. One subgroup, patients 10 years or older, appeared to benefit from debulking surgery (EFS 73% vs. 50%, $P = .04$; OS 83% vs. 62%, $P = .06$), but no other subgroup defined by site, size, histology, invasiveness, or response to initial chemotherapy did so.[333]

In patients with gross residual disease when chemotherapy begins (group III and IV), second-look operations and delayed excision of residual tumor masses, even after radiation therapy and chemotherapy, may improve the chances for survival. In a retrospective study of second-look operations in IRS-III, 12% of patients clinically believed to have had a complete response had residual viable tumor and three fourths of patients clinically believed to have had a partial response or no response either had no viable tumor or were converted to a complete response at surgery. These "converted" patients had the same 3-year survival as those whose complete responses were confirmed at second-look surgery (73% and 80%, respectively).[331] A single-institution study of 48 group III patients showed that those who had a delayed complete surgical excision (n = 22) had superior RFS and OS to those who did not (approximately 90% vs. 60% RFS, $P = .013$).[334] Patient numbers were too small to permit a multivariate analysis, however, and histology and nodal status were also significant variables on univariate analysis.

Radiation Therapy

Because RMS can often occur in sites that are not amenable to surgery, radiation therapy has a key role in primary tumor treatment. Advances in radiation therapy techniques are reducing the acute and late morbidities of treatment. However, there are large gaps in our knowledge of how best to use radiation to treat RMS.

The first knowledge gap is to determine who needs radiation therapy. A retrospective analysis of 439 group

I patients in IRS-I, IRS-II, and IRS-III found no benefit from irradiation for patients with embryonal tumors for OS (95% at 10 years for both groups, $P = .83$). For alveolar and undifferentiated tumors, however, each of the IRS studies showed a benefit from radiation therapy, analyzing by treatment received.[335] Subsequently, an analysis of IRS-III and IRS-IV data found no EFS or OS advantage for radiation therapy in alveolar stage 1 and 2 tumors but it remained important for patients with stage III tumors.[336]

A retrospective analysis of the CWS-81, CWS-86, CWS-91, and CWS-96 studies showed that the use of radiation therapy roughly halved the risk for death for patients with embryonal tumors smaller than 5 cm ($P = .02$) and for patients with larger embryonal tumors ($P = .001$) but had a smaller effect for patients with alveolar tumors (risk of death ratio 0.7, $P = .09$).[287] Another analysis of the same studies focused on 203 patients with group II tumors (microscopic residual disease at diagnosis). It compared the 110 patients who received radiation therapy with the 93 who did not (for a variety of reasons). The two groups of patients differed significantly in histology (more irradiated patients had alveolar tumors), site (more extremity and parameningeal tumors, and fewer vaginal-paratesticular tumors, among the irradiated patients), and age (fewer infants among the irradiated patients). All patients received combination chemotherapy according to one of several regimens. Despite the greater number of unfavorable characteristics among the irradiated patients, their local control was better (83% vs. 65%, $P < .04$), and their EFS was better (76% vs. 58%, $P < .005$), although the OS rates of the irradiated and unirradiated patients were similar (84% and 77%).[337] In the IRS studies I through IV there were 37 patients with group II tumors who did not receive radiation; their FFS was 69%, and OS 85%, which was very similar to the 73% and 78%, respectively, for the entire cohort.[338] Thus radiation therapy probably confers an advantage to group II patients but it is far from indispensable for local control and survival.

The management of patients with initially unresected tumors (Group III) who have delayed excisions is also a contentious issue. The IRS and subsequent COG protocols have required radiation therapy for these patients, although European protocols have not. A single institution study of 48 patients with group III RMS identified 22 who had complete excisions at second-look surgery, of whom 13 were treated with subsequent radiation and 9 were not. One patient in each group experienced relapse ($P = .67$), neither at the primary site.[334] In the MMT-89 study, 58% of the 289 survivors with "incomplete" initial surgery or biopsy only had either chemotherapy alone or chemotherapy plus "conservative" local therapy (defined as no functional deficits and no external-beam irradiation).[339] Unfortunately, these patients are not classified by stage or site, but radiation therapy was not indispensable for cure. Similarly, the CWS-86 study had 31 group III patients who did not receive radiation therapy (16 because of age <3 years), again not classified by site or histology. All but 1 had a complete response to chemotherapy and surgery. The local relapse rate was 27%, versus 10% for patients receiving radiation ($P = .2$), and the overall relapse rate was 40%, versus 28% for irradiated patients ($P = .001$).[282] Thus, although radiation therapy seems to reduce the local recurrence risk and improves the survival rate for patients with group III tumors, it is not indispensable.

Assuming the use of radiation therapy, the question becomes how much radiation the different presentations of RMS require to maximize the chances for cure. At the low side of the dose-response curve, it is unclear how much radiation is advisable. A single-institution study of 32 patients with IRS group II RMS (all but two embryonal histology) used chemotherapy (vincristine, doxorubicin, actinomycin, cyclophosphamide, with or without methotrexate, bleomycin, and carmustine) and from 30 to 60 Gy of radiation. Nineteen patients received 40 Gy or less, with only one local relapse; 14 received 36 Gy or less, with the same single local failure.[340] The CWS-86 study compared 67 group III patients who received 25 to 35 Gy (mean 31.6 Gy) with 49 patients who received 40 to 67 Gy (mean 52 Gy); 31% of the lower-dose group and 26% of the higher-dose group experienced relapse, although a higher proportion of the relapses in the higher-dose group were metastatic rather than local or regional.[282] In this study, the higher doses of radiation seem to have reduced the risk for local recurrence. The COG D9602 study of low-risk RMS used lower doses of radiation for selected patients: 36 Gy for patients with microscopic residual, N0 disease (41.4 Gy in earlier studies), and 45 Gy for patients with orbital tumors (had been 50.4 Gy). The local relapse rates were higher than in IRS-IV, but changes in chemotherapy for orbital and vaginal tumors (elimination of cyclophosphamide or ifosfamide) complicated the analysis. The authors concluded that the lower radiation doses do not lead to poorer local control, provided that cyclophosphamide is part of the chemotherapy.[341,342]

At the high side of the dose-response curve, IRS-IV randomized patients with group III tumors between 50.4 Gy by conventional fractionation (180 cGy/day) and 59.4 Gy by hyperfractionation (110 cGy twice daily). The hyperfractionated regimen was designed to allow a higher dose without an increase in late effects. There was no difference in any outcome measure between the two regimens (FFS, OS, local relapse, distant relapse) and no difference according to histology.[293] This indicates that 50.4 Gy is sufficient to control most gross residual RMS; less radiation may be equally efficacious.

In an effort to spare normal tissues from radiation, some institutions have used brachytherapy at the time of second-look surgery.[343-346] This technique usually involves the placement of catheters in the tumor or tumor bed during surgery; the catheters are subsequently loaded with radioactive pellets and then removed when the dose is complete. The brachytherapy dose often needs to be supplemented with external-beam radiation, and we have found that intensity-modulated radiation therapy (IMRT) and proton therapy have largely replaced brachytherapy.

Some institutions have also used intraoperative radiation therapy (IORT), which involves the delivery of a single large fraction of external-beam radiation with the tumor or tumor bed surgically exposed. Generally, larger radiation fractions decrease the therapeutic index, especially for late effects, and this may be the case in pediatric IORT. One series of seven children treated with IORT for neuroblastoma followed for 4 to 143 months (median 38 months) after irradiation; all 7 had hypertension, 5 had vascular stenosis in the radiation field, and 2 patients died in remission (one of mesenteric artery stenosis and bowel ischemia and another of massive ascites).[347] Similarly, of eight surviving patients in another series treated for a variety of pediatric solid tumors, 2 patients required surgery for hydronephrosis and small bowel obstruction, a third developed severe renovascular hypertension and superior mesenteric artery stenosis, and 2 developed neuropathies.[348] In another series, 3 of 14 children treated with IORT for recurrent brain tumors developed radiation necrosis within 6 to 12 months.[349] However, the largest reported series of IORT-treated children (n = 59) who had a variety of malignancies, recorded no long-term toxicities among the 14 long-term survivors.[350]

Proton therapy minimizes the irradiation of normal tissues surrounding the target, and its resulting potential to decrease late effects makes it particularly attractive for treating children. Proton therapy is currently available only at a small (but growing) number of centers, and there are few systematic evaluations. A comparison of conformal radiation, IMRT, and proton plans for a patient with parameningeal RMS calculated that protons reduced the risk for a second malignant neoplasm by a factor of two or more.[351] A retrospective study of 17 consecutive children with parameningeal RMS found 4 with local recurrences (of whom 3 had had intracranial extension at diagnosis), and late effects that were similar to or less frequent than those reported in other studies.[352] Ten of those patients had both proton and IMRT plans, and a comparison of them showed that the two techniques provided equally good coverage of the target volumes but the proton fields greatly reduced the irradiation of normal tissues (by factors of twentyfold to over fiftyfold for median doses to contralateral structures), except for the ipsilateral cochlea and mastoid.[353] Another study compared the proton and three-dimensional conformal radiotherapeutic plans of seven patients treated with protons for orbital RMS. Proton therapy reduced the radiation dose to the hypothalamus, pituitary, temporal lobes, and optic chiasm by 82% to 94% and reduced the dose to the ipsilateral lens by 65%.[354] Similarly, an analysis of 7 consecutive patients with bladder-prostate RMS showed that proton therapy statistically significantly reduced radiation doses to the bladder, testes, femoral heads (sixfold), growth plates, pelvic bones, and bone volume compared with IMRT. Rectal, prostatic, and bowel doses were not significantly affected.[355] More patients, longer follow-up, and application of objective criteria will be necessary to determine whether the lower doses lead to fewer or milder late effects.

The last radiation therapy variable is timing, which has been most controversial in parameningeal RMS. Different IRSG and COG protocols have called for radiation for parameningeal RMS to begin at times ranging from the first week of treatment to the twelfth. Earlier radiotherapy was associated with better survival in IRS-II and IRS-III, although there were so many other changes in treatment that its role cannot be isolated.[291] A recent analysis of consecutive studies has settled the question. In IRS-IV, patients with parameningeal RMS and cranial nerve palsies or cranial base bony erosion had irradiation during the first week, and similar patients in COG D9803 had irradiation beginning in the twelfth week; patients with no such risk factors had irradiation beginning at weeks 6 to 9 in IRS-IV and week 12 in COG D9803. For all parameningeal RMS patients, the 5-year local failure rate, FFS, and OS were almost identical in the two studies (19% local failure in both, $P = .67$; FFS 70% vs. 67%, $P = .32$; OS 75% vs. 73%, $P = .45$). There were also no statistically significant or consistent differences in local failure rates within the groups of patients with and without intracranial extension or cranial nerve palsies.[356] There appears to be no advantage to earlier radiation therapy in RMS; in fact, there may be an advantage to later irradiation through reduction of late effects. A single-institution study of 22 patients with parameningeal RMS showed that the use of delayed irradiation with a shrinking field technique reduced the mean treated area by half, from 99 cm^2 before chemotherapy to 48 cm^2 after chemotherapy, with no apparent effect on RFS.[357]

Special Situations

Infants and Toddlers

Infants with RMS differ from older children in the characteristics of their tumors, their treatment, and their responses to treatment and outcomes. An analysis of 76 infants (age <1 year) treated on IRS-IV and IRS-V showed fewer embryonal and more undifferentiated and other histologies in infants than in older children (ages 1 to 9 years). Infants also had more tumors of the limbs, trunk, bladder-prostate, and abdomen and fewer tumors of the parameningeal sites and orbit.[273]

Treating small children with unresectable (group III) tumors without devastating late effects can be difficult, because tissues irradiated to the doses used for RMS will not grow. Results with very young patients treated without radiation challenge the dogma that radiation therapy is essential for cure of all but group I patients. In the CWS-86 study, 30 patients with stage III (equivalent to group III) tumors, about half of them younger than age 3 years, were treated without radiation therapy, having achieved a complete response with chemotherapy and surgery. Twelve of the 30 (40%) experienced relapse, and 8 (27% of the 30 patients) had local recurrences, for a progression-free survival (PFS) rate of about 60%.[282] Although this was similar to the EFS rate for stage III patients with a complete response to initial therapy in this study, the patients are not classified according to other risk factors (such as site), and the numbers are too small for statistically meaningful comparison. In the IRS-IV and IRS-V analysis, 23 of 72 infants with group III tumors received no radiation; their 5-year FFS was inferior to that of the group receiving radiation (32 vs. 47%, $P = .17$), but the OS was similar (58% vs. 63%, $P = .49$).[273]

Infants and toddlers also appear to tolerate aggressive chemotherapy less well than older children. In the COG D9803 intermediate-risk study, which used VAC with a single dose of dactinomycin and 2.2 g/m^2 of cyclophosphamide, there were 18 cases of hepatopathy resembling sinusoidal obstructive syndrome, 4 of them fatal.[358] The total incidence of hepatopathy among 339 eligible patients was 6%, but it was 14% for patients younger than 36 months and only 4% for older patients. A modification of dactinomycin and cyclophosphamide doses for young patients ameliorated the problem. Cooperative group protocols have varying schemes for calculating infant chemotherapy doses (such as using a weight basis rather than a surface area basis), but none has a foundation in data.

The effects of these compromises on outcome is unclear. A retrospective analysis of IRS-COG studies from 1984 through 1997 (IRS-III, IRS-IV pilot, and IRS-IV) found that patients younger than 1 year of age have a much lower FFS than patients aged 1 to 9 years and one similar to that of adolescents (age ≥ 10 years) (53% v. 72% vs. 52%, $P < .001$)[272]; the infants with nonmetastatic RMS in IRS-IV and IRS-V did similarly.[273] In contrast, the SIOP MMT-84 and MMT-89 studies compared infants (<1 year of age) with localized RMS to children aged 1 to 9 years and adolescents 10 years and older and found identical EFS and OS rates between the infants and older children, both of whom did better than the adolescents (EFS 57% vs. 58% vs. 42%; OS 72% vs. 72% vs. 59%, $P < .001$ between adolescents and the other groups).[359] The infants more often had alveolar histology than older children and also more often had bladder-prostate and limb primary sites. In the earlier IRS study and the MMT studies there was no analysis of deviations from protocol therapy, whereas the later COG analysis showed many deviations from protocol-prescribed radiation therapy but few from prescribed chemotherapy. It remains unclear how reductions in therapy and biologic differences contribute to the inferior outcomes.

Bladder and Prostate Tumors

Because RMS can occur anywhere in the pelvis, and because pelvic tumors are often very large at the time of diagnosis, the exact primary site may be difficult to determine. One should not assume that a pelvic RMS is arising from the bladder or prostate without definitive imaging or cystoscopy. Bladder-prostate tumors usually produce urinary symptoms and are rarely alveolar histology, so one should be especially suspicious that tumors without these characteristics are arising in nongenitourinary pelvic sites. This distinction can have large implications for primary tumor treatment.

The evolution of approaches to bladder-prostate RMS can be traced through the IRS trials. Early approaches included extensive surgery (often complete or partial pelvic exenteration) in addition to chemotherapy. In IRS-I, more than half of the patients with bladder-prostate RMS had initial excisions (group I or group II), often involving anterior exenteration or cystectomy. At 5 years the DFS rate was 67% and the OS rate was 76%. The effectiveness of chemotherapy led to efforts to use initial chemotherapy and postpone and reduce surgery in favor of radiation therapy in hopes of preserving genitourinary anatomy and function. When this approach was taken in IRS-II, the proportion of group I or II patients decreased to 5%. However, the DFS rate declined substantially (to 51%), although the OS was comparable (71%). The new approach had no effect on the proportion of patients alive and with intact bladders, however, which were 23% in IRS-I and 22% in IRS-II.[360] The IRS-III study used more intense chemotherapy (all patients receiving VAC plus doxorubicin, cisplatin, and etoposide), radiation therapy beginning at week 6, and second-look surgery at week 20. The fraction of patients retaining their bladders rose to 60%, with PFS and OS rates improving to 74% and 83%, respectively.[292,361] IRS-IV used different chemotherapy, moved the radiation therapy from week 6 to week 9, and encouraged second surgical procedures short of complete cystectomy or prostatectomy unless there was biopsy-proven residual tumor at the end of therapy or progression. The OS rate of the 88 reviewed patients was 82%, the FFS rate was 77%, and 63% of patients retained their bladders.[362] A retrospective study of 63 CWS patients produced similar results, with an approach that varied the radiation dose and fractionation for group II and III patients according the response to initial chemotherapy.[363] As discussed previously, a comparison of results from the Italian, SIOP MMT, German CWS, and IRS/COG studies showed statistically insignificant variations in EFS despite the groups' different approaches, and no difference in OS (range, 79% to 85%; $P = .93$).[324]

There have been two problems with these bladder-preserving strategies: often the bladders do not work very well, and the collateral side effects can be considerable. Radiation therapy can cause fibrosis of the bladder and sphincters, leading to limited bladder capacity, dribbling, or incontinence. Radiation therapy to the pelvis limits bony growth, and even with modern IMRT techniques it can be difficult to avoid irradiation of the hip joints, leading to future orthopedic problems. A review of IRS-I and IRS-II patients, which involved asking physicians whether their patients' urinary function was normal, found "normal" urinary function in 73% of the 52 patients who had retained all or part of their bladders; the remaining 27% had incontinence, frequency, or nocturia. Radiation therapy and cyclophosphamide (before mesna's availability) combined to produce hematuria after completion of treatment in 20%. Outside the urinary tract, spontaneous reporting disclosed 4 patients with colostomies to repair fistulas or relieve strictures and 6% with fecal incontinence, chronic diarrhea, or rectal stenosis. Eight percent had orthopedic problems, including slipped femoral epiphyses, and pelvic fibrosis or hypoplasia.[364]

A more recent study of IRS-IV patients used routine follow-up forms and questionnaires to physicians. Of 55 patients with preserved bladders, two thirds were reported to have normal urinary function while the balance had late diversions, dribbling, incontinence, enuresis, hydronephrosis, or strictures. Interestingly, no differences in relapse rate or pattern could be found between patients who had protocol-specified radiation therapy and those who had major deviations in radiation therapy (including 9 who received none), although 2 irradiated patients developed second malignancies.[362]

The cooperative group data may underestimate the frequency and severity of late effects in this population, however. A single-institution study of 26 girls cured of pelvic RMS (including nonbladder sites) found that 23 (88%) had grade III or IV late effects at a median of 20 years follow-up, with over half requiring surgery for these complications. The most common problems were musculoskeletal hypoplasia, recurrent urinary tract infections, incontinence, urinary reflux, and short stature. There were three secondary solid tumors in radiation fields. Radiation therapy was associated with more late effects per patient ($P = .002$), and patients treated since 1984 had about twice as many late effects per patient than patients treated earlier (12.5 vs. 6.5, $P = .041$).[365]

None of these studies used urodynamics to measure bladder function objectively. One single-institution study that did so had 11 patients with pelvic RMS (7 with tumors of the bladder or prostate) and found that all 7 patients who had received radiation therapy had markedly reduced bladder capacity (11% to 48% of age norms) and abnormal voiding patterns; 4 had upper tract abnormalities, and 2 had severe bilateral hydronephrosis.[366]

Bladder-prostate RMS is unusual in that one can monitor the tumor easily with cystoscopy and biopsy. In view of the considerable late effects of radiation therapy in particular, some centers use cystoscopic and histologic monitoring to delay and minimize the use of irradiation, moving in the direction of the SIOP MMT studies.[367] This requires expert pathologic interpretation, however, because distinguishing between viable RMS and harmless differentiated rhabdomyoblasts can be very difficult, especially in the field of previous surgery or radiation therapy.[367,368]

Vaginal Tumors

Excellent survival rates make the female genitourinary tract a favorable site in RMS trials but one fraught with anatomic, late effects, and emotional difficulties. In the young girls in whom this tumor most often occurs, the vagina is very small, very thin-walled, deep in the pelvis, and sandwiched between the urethra (and bladder, if distended with tumor) and the rectum. The late effects of complete or partial excision are severe, as can be the effects of radiation therapy (on both the soft tissues and nearby hips). The use of chemotherapy and conservative surgery alone is thus very attractive.

A retrospective survey of female genitourinary RMS patients on the MMT-84 and MMT-89 studies, which used the SIOP strategy of relying on chemotherapy (IVA regimen) and avoiding local therapy whenever possible, included 38 patients. Four had initially complete excisions with conservative surgery and survived event free; 13 had incomplete excisions and chemotherapy with no further local therapy and were event-free survivors; and 17 required local therapy for microscopic or gross residual tumor after initial chemotherapy. This was radical surgery in 6 patients, radiation in 10, and conservative surgery in 1. Although it is extremely difficult to trace the 38 patients through their treatment, the data showed that about half of girls with genitourinary RMS were cured with the IVA chemotherapy regimen without radical surgery or irradiation.[369]

More recently, the COG reviewed vaginal RMS treated on the consecutive low-risk studies D9602 and ARST0331. On the former study, group I and IIA (microscopic local disease) patients received 45 weeks of vincristine-dactinomycin, whereas patients with regional nodal involvement or gross residual tumor (groups IIB, IIC, and III) received 45 weeks of VAC. In ARST0331, patients received four cycles of VAC (with a lower dose of cyclophosphamide; see Table 59-9) and then VA to a total of 24 weeks (groups I and IIA) or 46 weeks (all others). Local therapy was based on response assessments beginning at week 11 to reduce or avoid radiation. Of 37 group IIA or III patients, only 4 received radiation; 4 had tumor progression before local treatment. However, the local recurrence rates were 26% and 43% on D9602 and ARST0331, respectively, and there appeared to be a strong relationship between total cyclophosphamide dose and risk of local recurrence. Therapy after recurrence was not collected systematically, but OS was excellent despite the local recurrences (100% on D9602 and 94% on ARST0331).[370] Successful treatment of vaginal RMS without mutilating surgery or irradiation appears possible using alkylating agent–containing chemotherapy (VAC or IVA regimens) and careful local surveillance. Fortunately, females are much less likely than males to be sterilized by alkylator chemotherapy.

Parameningeal Tumors

The parameningeal sites include the nasal cavity and nasopharynx, parapharyngeal space, paranasal sinuses (ethmoid, maxillary, and sphenoid), the pterygopalatine and infratemporal fossae, and the middle ear and mastoid sinuses. Parameningeal RMS has a tendency to invade the cranium and intracranial contents, either by eroding through the skull base or by extending through a foramen. Curiously, tumors arising in the orbits are much less aggressive. Complete excision of parameningeal tumors at diagnosis is almost never possible, so that they are at best stage II, group III in the IRS-COG staging system. The vast majority are of embryonal histology.

In the IRS-I study, 5-year OS was only 47%[280]; it was identical in CWS-81.[371] The IRS-II study intensified therapy for patients with parameningeal tumors with craniospinal radiation and intrathecal chemotherapy (methotrexate, cytarabine, and hydrocortisone) beginning immediately after diagnosis, and OS improved to 67%.[281,372] IRS-III substituted whole-brain for craniospinal radiation therapy and began it early only for patients with cranial nerve palsies or intracranial extension or base-of-skull erosion on imaging; chemotherapy was also considerably more intense. Survival improved again, to 73%, but 5 patients (3.4%) developed ascending myelitis, which was fatal in 3.[373] In IRS-IV, intrathecal chemotherapy was eliminated, and the radiation field was reduced to the involved area with a 5-cm margin, with no loss of efficacy found on a retrospective analysis of 611 IRS II-IV patients.[372]

A univariate analysis of parameningeal RMS patients in IRS II and IRS-IV identified age between 1 and 9 years; site in the nasal cavity, nasopharynx, parapharynx, middle ear, or mastoid; and lack of bony erosion or intracranial extension as favorable features.[372] Patients with entirely favorable features had a 92% OS at 5 years, compared with 57% for those with entirely unfavorable features. Size and histology were not statistically significant factors.

Results in Europe lagged far behind, with 5-year OS 55% in SIOP, 47% in Germany, and 39% in Italy.[374] An international workshop in 1994 combining the American and European experience recommended routine use of MRI to define the extent of the tumor; treatment of all parameningeal RMS patients with radiation therapy (in the SIOP-84 study 18 of 44 had not been irradiated, with only 5 surviving); a minimum dose of 50 Gy with a 2-cm margin; and routine external quality control of radiation.[374]

Recent results have largely settled the long-running controversy over the timing of radiation in parameningeal RMS, as discussed in an earlier section.

Relapsed Rhabdomyosarcoma

The prognoses of patients whose RMS relapses are highly variable, but mostly depend on initial tumor characteristics and treatment. An analysis of survival after relapse in 605 IRS-III, IRS-IV pilot, and IRS-IV patients showed 5-year survival rates ranging from 3% (for patients with alveolar histology and originally group II through group IV tumors) to 72% (for patients with originally stage I or group I tumors and embryonal histology).[375] The median survival for all relapsed patients was 9.8 months, and OS was 17% at 5 years. Postrelapse survival for patients with embryonal histology was far better than for those with alveolar or undifferentiated tumors, but other prognostic factors were different for the two histologic groups.

An analysis of relapsed patients from Italian RMS studies (n = 125) identified metastatic relapse, unfavorable primary site, alveolar histology, and relapse or progression during initial therapy to be unfavorable features. When each of those was used as a risk factor, the 5-year survival ranged from 72% with no risk factors to nil with three or four factors.[376] The analysis only included patients with initially localized tumors, which may be why the median survival after relapse (15.4 months) and 5-year OS (28%) were better than those observed in the IRSG study.

The most sophisticated analysis of postrelapse survival was based on nonmetastatic patients who experienced relapse after treatment on the SIOP MMT-84, MMT-89, and MMT-95 studies (n = 474). Two thirds of the relapsed patients had not had irradiation as part of their original treatment, reflecting the philosophy behind the studies. In a multivariate analysis, the prognostic variables were the type of chemotherapy (2, 3, or 6 drugs), histology, nodal status, primary site, original size, metastatic or local recurrence, radiation therapy as part of initial treatment, and time to recurrence. These eight variables were combined into a nomogram, permitting estimation of prognosis for an individual patient.[377] The remarkably high OS rate (36% at 5 years) reflects the exclusion of patients whose tumors were metastatic at diagnosis, and the omission of initial radiation therapy in a large proportion of patients.

For treatment of relapsed RMS, after a COG trial in patients with metastases at diagnosis demonstrated that vincristine-irinotecan was superior to vincristine alone,[314] the COG conducted a randomized controlled trial in relapsed patients of two schedules of vincristine-irinotecan “window” therapy followed by five-drug alternating chemotherapy (vincristine-doxorubicin-cyclophosphamide/ifosfamide-etoposide). This showed that a 5-day schedule with irinotecan 50 mg/m^2/day was less toxic, and at least as effective, as a “daily × 5 × 2” schedule that used 20 mg/m^2/day irinotecan for 5 days on 2 consecutive weeks. Unfortunately, the median survival remained dismal at 1.3 and 1.4 years, as did FFS (14% and 15% at 3 years).[315] The most recent COG study (ARST0921) was a randomized phase II trial comparing bevacizumab and temsirolimus added to concurrent vinorelbine and cyclophosphamide. The results are pending.

Megatherapy for Metastatic and Recurrent Rhabdomyosarcomas

A perennial question in the treatment of patients with metastases at diagnosis, or who have experienced relapse, is the role of megatherapy: high-dose chemotherapy, with or without total-body irradiation, with autologous (occasionally allogeneic) stem cell or marrow transplantation. The analytic problems are large: there are vast differences between different populations of patients with metastases, with 3-year survivals ranging from 5% to 47% and an even wider range of prognoses for patients with relapsed RMS (see earlier). There are also wide variations in entry criteria for megatherapy studies, ranging from having a complete response to initial salvage chemotherapy, to failing to achieve a complete response to initial chemotherapy. Often, the entry criteria and key terms (e.g., “high risk”) remain undefined. For all these reasons, reports of results of megatherapy in RMS merit careful scrutiny (see the excellent review by Meyers[378]).

Two recent systematic reviews of high-dose therapy in metastatic RMS could find no randomized controlled trials, and only two historically controlled trials, each with serious methodologic limitations and potential biases. The reviews concluded that there is no evidence to justify the use of megatherapy in metastatic RMS patients outside a controlled clinical trial.[379,380] Until randomized controlled trials are performed, the role of megatherapy in RMS will remain dubious.

FOLLOW-UP AFTER TREATMENT

Surveillance and Patterns of Recurrence

Examination of Kaplan-Meier plots of many studies of newly diagnosed RMS shows that the vast majority of failures (progression or relapse) occur in the 3 years after diagnosis, although they can occur even 9 years after diagnosis. The complex nature of RMS persists as complex patterns of failure, varying by primary site and histology, and being local, regional (lymph nodes), metastatic, or any combination. In IRS-III, for example, local failures outnumbered distant ones by 7:1 among patients with orbital primary tumors; but among patients with extremity primary sites, distant and combined failures outnumbered local ones by almost 7:1. Among patients with embryonal histology tumors, local failures outnumbered combined and distant failures by about 2:1; but among patients with alveolar and "other" histology, combined and distant failures were more common.[381]

In the same analysis of failure patterns in IRS-III, univariate analysis identified N1 (clinically positive) nodal status as the key risk factor for local or combined local and regional or distant failure; N1 nodal status was, in turn, associated with older age, alveolar histology, large (>5 cm) tumors, and unfavorable primary sites.[381] Distant failure was most likely in patients with N1 nodes and primary tumors in limbs.

A review of IRS-IV data showed that achievement of a complete response at the end of therapy (no residual tumor present on examination and conventional imaging) appears to have no effect on prognosis in group III RMS patients; nor does it influence local, regional, or distant failure rates (e.g., complete vs. partial or no response 13.5% vs. 13.5% for local failure). Similarly, resection of a residual mass at the end of therapy did not appear to improve outcome.[382]

Failure patterns appear to have changed across the first three IRS studies, but this may be due to shifts in definitions and classifications. Attention to definitions is again necessary when assessing reports, because, for example, failures in regional lymph nodes may be considered local (if they were within the radiation therapy field), regional, or distant.

The follow-up intervals and procedures prescribed in COG RMS protocols reflect the changes in risk over time. They include a history, physical examination, and chest imaging (radiograph or CT) every 3 months during the first year off therapy, every 4 months during the second and third years, and every 6 months during the fourth year, with primary site imaging depending on the site and the primary tumor treatment used. During and annually after this follow-up for tumor recurrence, monitoring for late effects of treatment is also necessary, especially for tissues in a radiation field.

Late Effects

The late effects of childhood cancer and its treatment are discussed thoroughly in Chapter 71. In patients treated for RMS, most observed late effects are from the tumor itself (e.g., cranial nerve palsies from parameningeal tumors), surgery, and radiation therapy. Radiation therapy sequelae are particularly problematical because of the young ages of many of the patients and the locations of their tumors.

Chemotherapy late effects particularly relevant to RMS include late hemorrhagic cystitis from cyclophosphamide and ifosfamide and secondary myelodysplasia or leukemia. Ifosfamide may cause a nephropathy, which is occasionally progressive.[383] Relatively few patients treated on current protocols receive anthracyclines (with their attendant risk of late heart disease) or cisplatin (with its hearing loss and renal dysfunction). Sterility in males and early menopause in females may result from the high doses of alkylating agents used.

FUTURE DIRECTIONS

Among ERMS there is an enormous range of clinical behavior that varies with site and age. Fusion-bearing ARMS is a highly aggressive tumor, with the PAX7-FOXO1–bearing variant perhaps being less so. However, we remain far from having molecularly based classification of RMS that correlates with, much less explains, the enormous variations observed in clinical behavior, especially among embryonal (fusion-negative) tumors. Techniques such as gene expression profiling, application of epigenetic analyses, and increasingly sophisticated evaluation of combined clinical and laboratory data may allow us to discern the combinations of tumor and host variables that make, for example, a paratesticular ERMS much more aggressive in a teenager than in a preschooler.

More sophisticated classification opens opportunities for "tailoring" chemotherapy but also presents the challenge of smaller populations of patients for study. In the COG, it is already barely statistically feasible to carry out randomized controlled trials with intermediate-risk patients in 5 years. International collaboration has the benefit of providing larger patient numbers, but having fewer studies means that fewer ideas are tested. The bureaucratic and regulatory barriers are also formidable. The path through these obstacles is not obvious.

Therapeutically, there are two challenges: identifying promising new agents and integrating them into existing therapy. One cannot predict which of the many newly discovered biochemical pathways and small molecule inhibitors will lead to improvements in outcome in RMS patients. The numbers of patients are too small to provide an attractive market for the pharmaceutical industry, so an agent that would, for example, specifically block the action of the PAX-FOXO1 fusion proteins is unlikely to become available. Downstream of the fusion proteins lay potential pharmacologic targets that may well be commercially interesting, however. Immunotherapy is a possibility for the future if appropriate antigens can be found and paired with the appropriate technology.[384]

The quest for new targets and agents is very unlikely to lead to a "magic bullet" that makes current therapy obsolete. Thus we must continue our efforts with "traditional" chemotherapy and carefully integrate new agents. The closest to clinical application are probably the tyrosine kinase inhibitors (particularly pazopanib) and "rapalog" mTOR inhibitors, but the former have only been tested in mice, and one of the latter is in a phase II trial in combination with chemotherapy. Large improvements in outcome have occurred in the leukemias in the past decade, with a collection of drugs that are at least 25 years old; one of the advantages of that disease system is easy evaluation of response through marrow aspiration. Good early response markers (perhaps PET) could extend the same advantage to RMS and other solid tumors.

CHAPTER 60

Nonrhabdomyosarcoma Soft Tissue Sarcomas and Other Soft Tissue Tumors

Ian J. Davis, Antonio R. Perez-Atayde, and David E. Fisher

CHAPTER OUTLINE

EPIDEMIOLOGY
PRESENTATION AND EVALUATION
STAGING AND GRADING
TREATMENT
Local Control
Chemotherapy
GENERAL BIOLOGIC FEATURES
ADIPOCYTIC TUMORS
FIBROBLASTIC AND MYOFIBROBLASTIC TUMORS
Desmoid Tumor
Infantile Myofibroma/Myofibromatosis and Hemangiopericytoma
Infantile Fibrosarcoma
Fibrosarcoma Arising in Dermatofibrosarcoma Protuberans and Giant Cell Fibroblastoma
Low-Grade Fibromyxoid Sarcoma
Myxofibrosarcoma
Solitary Fibrous Tumor
Inflammatory Myofibroblastic Tumor
SO-CALLED FIBROHISTIOCYTIC TUMORS
Plexiform Fibrohistiocytic Tumor
SMOOTH MUSCLE TUMORS
Sporadic Leiomyosarcoma
Leiomyosarcoma Associated with the Epstein-Barr Virus
VASCULAR TUMORS
Epithelioid Hemangioendothelioma
Giant Cell Angioblastoma
Kaposiform Hemangioendothelioma
Kaposi Sarcoma
Angiosarcoma
CHONDROOSSEOUS TUMORS
Mesenchymal Chondrosarcoma
Extraskeletal Myxoid Chondrosarcoma
TUMORS OF UNCERTAIN DIFFERENTIATION
Synovial Sarcoma
Alveolar Soft Part Sarcoma
Clear Cell Sarcoma
Desmoplastic Small Round Cell Tumor
Angiomatoid Fibrous Histiocytoma
Extrarenal Rhabdoid Tumor
Epithelioid Sarcoma
Extraosseous Ewing Sarcoma
Gastrointestinal Stromal Tumor
Ectomesenchymoma
NEUROECTODERMAL TUMORS
Malignant Peripheral Nerve Sheath Tumors
Melanotic Neuroectodermal Tumor of Infancy
UNDIFFERENTIATED TUMORS
Undifferentiated Pleomorphic Sarcoma and Undifferentiated Round Cell and Spindle Cell Sarcoma

Soft tissue sarcomas of childhood and adolescence constitute a heterogeneous group of tumors that exhibit features of mesenchymal differentiation (Tables 60-1 and 60-2). From a pediatric oncology perspective, the various types of rhabdomyosarcoma, the most common soft tissue sarcoma in younger children, are grouped separately such that the remainder of these tumors are collectively termed the *nonrhabdomyosarcoma soft tissue sarcomas* (NRSTS). This term seems an odd eponym, defining a category of soft tissue sarcoma by exclusion and grouping together widely disparate clinicopathologic entities distinguished by clinical features, molecular pathogenesis, and biologic behavior. However, the term *NRSTS* carries a unique value in pediatric oncology, enabling the study of significant cohorts of children with uncommon tumors. Sarcomas in children represent a somewhat distinct set of tumors that diverge in both incidence and histology from those in adults. The types of sarcomas that develop in adolescents and young adults are similar to those seen in older individuals; however,

TABLE 60-1 World Health Organization Classification of Soft Tissue Tumors: Intermediate (Rarely metastasizing) and Malignant

	Intermediate (Rarely Metastasizing)	Malignant
Adipocytic		Dedifferentiated liposarcoma Myxoid liposarcoma Pleomorphic liposarcoma Liposarcoma, not otherwise specified
Fibroblastic/Myofibroblastic	Solitary fibrous tumor Dermatofibrosarcoma protuberans (fibrosarcomatous and pigmented) Inflammatory myofibroblastic tumor Low-grade myofibroblastic sarcoma Myxoinflammatory fibroblastic sarcoma (including atypical) Infantile fibrosarcoma	Adult fibrosarcoma Myxofibrosarcoma Low-grade fibromyxoid sarcoma Sclerosing epithelioid fibrosarcoma
So-Called Fibrohistiocytic	Plexiform fibrohistiocytic tumor Giant cell tumor of soft tissues	
Smooth Muscle		Leiomyosarcoma (excluding skin)
Pericytic (Perivascular)		Malignant glomus tumor
Skeletal Muscle		Embryonal rhabdomyosarcoma Alveolar rhabdomyosarcoma Pleomorphic rhabdomyosarcoma Spindle cell/sclerosing
Vascular Tumors	Retiform hemangioendothelioma Papillary intralymphatic angioendothelioma Composite hemangioendothelioma Pseudomyogenic (epithelioid-like) hemangioendothelioma Kaposi sarcoma	Epithelioid hemangioendothelioma Angiosarcoma of soft tissue
Chondroosseous		Extraskeletal mesenchymal chondrosarcoma Extraskeletal osteosarcoma
Nerve Sheath Tumors		Malignant peripheral nerve sheath tumor Epithelioid malignant nerve sheath tumor Malignant triton tumor Malignant granular cell tumor Ectomesenchymoma
Gastrointestinal Stromal Tumors		Gastrointestinal stromal tumors, malignant (AFIP groups 3b, 5, 6a, 6b)
Uncertain Differentiation	Ossifying fibromyxoid tumor Myoepithelioma Parachordoma	Synovial sarcoma (including spindle cell and biphasic) Epithelioid sarcoma Alveolar soft part sarcoma Clear cell sarcoma of soft tissue Extraskeletal myxoid chondrosarcoma Extraosseous Ewing sarcoma Desmoplastic small round cell tumor Extrarenal rhabdoid tumor Neoplasms with perivascular epithelioid cell differentiation (PEComa) (includes clear cell myomelanocytic tumor Intimal sarcoma
Undifferentiated/Unclassified		Undifferentiated spindle cell sarcoma Undifferentiated pleomorphic sarcoma Undifferentiated round cell sarcoma Undifferentiated epithelioid sarcoma Undifferentiated sarcoma, not otherwise specified

TABLE 60-2 World Health Organization Classification of Soft Tissue Tumors: Benign and Intermediate (Locally Aggressive)

	Benign	Intermediate (Locally Aggressive)
Adipocytic	Lipoma Lipomatosis Lipomatosis of nerve Lipoblastoma/lipoblastomatosis Angiolipoma Myolipoma Chondroid lipoma Extrarenal angiomyolipoma Extraadrenal myelolipoma Spindle cell/pleomorphic lipoma Hibernoma	Atypical lipomatous tumor/ well-differentiated liposarcoma
Fibroblastic/Myofibroblastic	Nodular fasciitis Proliferative fasciitis Proliferative myositis Myositis ossificans Fibroosseous pseudotumor of digits Ischemic fasciitis Elastofibroma Fibrous hamartoma of infancy Fibromatosis coli Juvenile hyaline fibromatosis Inclusion body fibromatosis Fibroma of tendon sheath Desmoplastic fibroblastoma Mammary-type myofibroblastoma Calcifying aponeurotic fibroma Angiomyofibroblastoma Cellular angiofibroma Nuchal-type fibroma Gardner fibroma Calcifying fibrous tumor	Palmar/plantar fibromatosis Desmoid-type fibromatosis Lipofibromatosis Giant cell fibroblastoma
So-Called Fibrohistiocytic	Tenosynovial giant cell tumor (localized and diffuse types and malignant) Deep benign fibrous histiocytoma	Plexiform fibrohistiocytic tumor Giant cell tumor of soft tissues
Smooth Muscle	Deep leiomyoma	
Pericytic (Perivascular)	Glomus tumor (and variants) Myopericytoma	
Skeletal Muscle	Rhabdomyoma (adult, fetal and genital types)	
Vascular Tumors	Hemangioma (synovial, venous, arteriovenous hemangioma/ malformation, lymphangioma) Epithelioid hemangioma Angiomatosis Lymphangioma	Kaposiform hemangioendothelioma
Gastrointestinal Stromal Tumors	Benign gastrointestinal stromal tumor (AFIP prognostic groups 1, 2, 3a)	
Nerve Sheath Tumors	Schwannoma Melanotic schwannoma Neurofibroma (including variants and plexiform neurofibroma) Perineuroma (malignant perineuroma) Granular cell tumor Dermal nerve sheath myxoma Solitary circumscribed neuroma Ectopic meningioma Nasal glial heterotopia Benign triton tumor Hybrid nerve sheath tumors	
Chondroosseous	Soft tissue chondroma	
Uncertain differentiation	Acral fibromyxoma Intramuscular myxoma Juxtaarticular myxoma Deep ("aggressive") angiomyxoma Pleomorphic hyalinizing angiectatic tumor Ectopic hamartomatous thymoma	Hemosiderotic fibrolipomatous tumor

the relative incidence and response to therapy may differ.[1] In addition, the term *NRSTS* permits the flexibility to include undifferentiated tumors and tumors that, based on treatment, are typically excluded from other groupings (e.g., desmoplastic small round cell tumor [DSRT]). Finally, by evoking those tumors prevalent in the pediatric population, the term *NRSTS* also permits consideration of the unique toxicities specific to children when evaluating treatment approaches and designing clinical trials.

NRSTS are often characterized by distinct, consistent cytogenetic, transcriptional, and intracellular signaling changes. Exploring these molecular alterations may offer insights into the biology of mesenchymal development and the pathogenesis of these tumors, thus leading to the development of new treatment strategies.

EPIDEMIOLOGY

In children younger than 5 years, rhabdomyosarcoma constitutes the most frequent type of soft tissue sarcoma (STS), however by late school age and continuing into adolescence the incidence of NRSTS rises to exceed that of rhabdomyosarcoma (Fig. 60-1). The total incidence for STS in children and adolescents younger than 20 years is approximately 11 per million, which represents 7.4% of cancer in this population.[2] NRSTS constitute about one half of these cases or 3% to 4% of childhood malignancies. Within the class of NRSTS, specific tumor types demonstrate a strong age association. Although the median age at diagnosis is approximately 13 years, NRSTS prevalent in younger children include infantile fibrosarcoma and rhabdoid tumor, whereas synovial sarcoma and malignant peripheral nerve sheath tumor (MPNST) are more common in adolescents.[3-9]

Although the vast majority of NRSTS occur spontaneously, several cancer predisposition syndromes are associated with the development of STS. Families that harbor mutations of the tumor suppressor gene *TP53* (i.e., those with Li-Fraumeni syndrome) are prone to the development of many types of cancer.[10,11] STS as well as osteosarcoma can be associated with germline *TP53* mutation.[12] The cell cycle regulatory protein RB has also been implicated in STS development. *RB* was originally identified as the locus deleted in hereditary and sporadic retinoblastoma.[13] However, retinoblastoma survivors are at risk for the development of STS, including fibrosarcoma, pleomorphic sarcoma, and leiomyosarcoma, and molecular analysis of these tumors may demonstrate homozygous *RB* deletion.[14,15] In addition to other tumors, neurofibromatosis type 1 (NF1, von Recklinghausen disease) is associated with the development of MPNSTs and multifocal gastrointestinal stromal tumors (GISTs).[16,17] Radiation therapy for optic nerve glioma in patients with NF1 increases the risk for subsequent MPNST development.[18,19] Carney triad is associated with multifocal GIST (as well as paragangliomas and pulmonary chondromas).[20,21] Individual Carney triad tumors are associated with specific nongermline mutations, although a possible common association with chromosome 1 changes has been reported.[22] Carney-Stratakis dyad, characterized by paraganglioma and GISTs, is associated with germline mutations in *SDHA, SDHB,* or *SDHC.*[23-25] Gardner syndrome, a phenotypic variant of familial adenomatous polyposis (FAP), results from mutation of the *APC* gene and is associated with an increased risk for abdominal desmoid tumor.[26-30] Gorlin syndrome, caused by mutation of the Hedgehog signaling pathway regulator *PTCH,* is associated with undifferentiated sarcoma.[31] Werner syndrome is caused by mutations of the deoxyribonucleic acid (DNA) helicase gene *RECQL2* or nuclear lamin gene *LMNA* and is associated with several cancers, including STS in early and middle adulthood.[32-34] Typically resulting from mutations in *TSC1* or *TSC2,* dominantly inherited tuberous sclerosis is associated with spontaneously resolving cardiac rhabdomyomas in infants and renal angiomyolipoma, including the malignant epithelioid variant, as well as pulmonary lymphangiomyomatosis.[35-38] Pleomorphic sarcoma in adults has infrequently been associated with Lynch syndrome, which is characterized by mutations in the DNA mismatch repair genes *MLH1* and *MLH2.*[39]

In addition to cancer predisposition syndromes, environmental exposures have been linked to sarcoma development. Although osteosarcoma predominates, radiation exposure is associated with NRSTS, including fibrosarcoma and pleomorphic sarcoma, with an incidence associated with the dose of radiation.[40-43] Of the several environmental chemical exposures that have been linked to the development of sarcomas in adults, vinyl chloride exposure demonstrates the strongest association to the development of angiosarcoma.[44] Childhood cancer survivors also appear to be at ninefold higher risk for the development of sarcomas (particularly NRSTS) in comparison with the general population, with a mean time from primary cancer diagnosis of 11 years.[45] Although an initial diagnosis of sarcoma was associated with the greatest risk, perhaps indicating an underlying predisposition, treatment with radiation or alkylating agents was also positively associated with sarcoma development. Epstein-Barr virus infection in individuals infected with human immunodeficiency virus (HIV) predisposes to leiomyosarcoma.[46]

PRESENTATION AND EVALUATION

NRSTS typically presents as a persistent or enlarging, asymptomatic mass. Although NRSTS may arise in any location, extremities constitute the most common sites. However, within the first year of life, soft tissue tumors tend to develop in the trunk and head and neck.[3] A significant fraction of tumors may be associated with pain that likely indicates invasion or compression of surrounding structures.[7]

The evaluation of NRSTS is typically initiated with appropriate imaging then followed by biopsy. For most tumors, plain radiography and magnetic resonance imaging (MRI) are justified. Technetium-99m–labeled methyldiphosphonate (^{99m}Tc MDP) nuclear scintigraphy can localize sites of bony metastatic disease. Because as a group these tumors tend to metastasize to the lungs, chest computed tomography (CT) is commonly indicated. Imaging may narrow the differential diagnosis and will aid in assessing resectability by identifying tumor margins, involved tissue planes, and relationship to neurovascular structures. Fluorine-18 (^{18}F)-labeled fluorodeoxyglucose (FDG) or ^{18}F-labeled fluorothymidine (FLT) positron emission tomography (PET) has been used for sarcoma staging, and combined PET/CT can identify primary tumors as well as metastatic spread and may detect metastatic lesions missed by bone scintigraphy.[47] However, small lesions (<1 cm) are difficult to visualize by PET. FLT-PET has been used to distinguish between low- and high-grade sarcomas.[48]

Accurate tissue diagnosis is critical to establish a treatment plan and to predict prognosis.[5] Because of the diverse range of sarcoma subtypes as well as their rarity, arriving at a definitive diagnosis can be challenging.[49] The complexity of NRSTS diagnosis and grading requires the integration of histopathology with immunohistochemical, ultrastructural, cytogenetic, and molecular studies (Table 60-3). Advance communication between the surgeon or interventional radiologist, pathologist, and pediatric oncologist can help ensure that sufficient material is obtained and suitably processed. Fine-needle aspiration often generates an inadequate specimen to yield a specific diagnosis. Multiple core needle biopsies may be sufficient to initiate the evaluation, with additional tissue resulting from eventual resection. Although sentinel lymph node biopsy is not a standard component of NRSTS evaluation, it could be considered for high-grade sarcomas such as clear cell sarcoma, synovial sarcoma, vascular sarcomas, and undifferentiated sarcomas.[50-52]

In general, sarcomas can be classified as those with a recognizable recurrent chromosomal rearrangement

(typically translocation) and those without. The identification of cytogenetic abnormalities, many of which are highly specific of certain pediatric and young adult NRSTS, is helpful in arriving at or confirming a diagnosis (see Table 60-3). However, the same gene can be translocated in different tumor types. For example, the *EWSR1* gene is rearranged in DSRT, clear cell sarcoma, myxoid liposarcoma, and a subset of undifferentiated sarcomas in addition to Ewing sarcoma. In contrast, the rearrangement of certain genes is highly restricted, such as *SS18* (*SYT*) rearrangement in synovial sarcoma. Molecular studies (e.g., polymerase chain reaction [PCR] assay and interphase fluorescence in situ hybridization [FISH]) may be required to evaluate for specific cytogenetic abnormalities, especially if there a high index of suspicion and standard cytogenetics are unavailable or unremarkable.[53] High-throughput DNA sequencing and other comprehensive genomic approaches have rapidly emerged as strategies to identify genetic alterations in sarcomas. Ongoing efforts to systematically identify mutations in select STS include the Pediatric Cancer Genome Project and the Cancer Genome Atlas. Although translocations can be detected relatively easily when sequencing the whole genome, owing to significant expense and technical considerations, most current high-throughput sequencing applications focus on exonic sequence variation and consequently are not designed to detect intronic breakpoints. However, RNA sequencing as well as whole exome and targeted sequencing of cancer-associated genes offers the potential to identify individuals with specific and therapeutically actionable mutations. To take advantage of emerging techniques for molecular analyses and biomarker identification, additional tumor material, if possible, should be preserved at −70° C for DNA or ribonucleic acid (RNA) analysis. For those sarcomas that may metastasize to the bone marrow, aspiration and biopsy may be performed to complete the evaluation for distant spread.

STAGING AND GRADING

As with all cancers, appropriate recommendations for therapy depend on accurate predictions of clinical course and prognosis. Clinically informative classification schemes will accurately predict tumor outcome and will aid in the development and interpretation of multicenter trials necessary to study these uncommon cancers. Studies of adult extremity STS suggest that grade followed by tumor depth and size are of independent prognostic value for the rates of distant metastases and tumor mortality.[54] However, the clinicopathologic classification of pediatric NRSTS poses unique challenges. The low incidence of these tumors results in grouping potentially disparate tumors in clinical trials. Patient age may influence outcome. For some tumors, high grade does not predict clinically aggressive behavior, whereas other tumors behave

TABLE 60-4 Children's Oncology Group Histologic Grading System

Grade	Description
1—Low	Myxoid and well-differentiated liposarcoma Well-differentiated or infantile (≤4 years old) fibrosarcoma Well-differentiated or infantile (≤4 years old) hemangiopericytoma Well-differentiated malignant peripheral nerve sheath tumor Extraskeletal myxoid chondrosarcoma
2—Intermediate	Sarcomas not specifically included in grade 1 and 3 and in which: • <15% of the surface area shows necrosis • Mitotic count is ≤5/10 high-power fields using a 40× objective • Absence of marked nuclear atypia* • Tumor is not markedly cellular*
3—High	Pleomorphic or round cell liposarcoma Mesenchymal chondrosarcoma Extraskeletal osteosarcoma Malignant triton tumor Alveolar soft part sarcoma Sarcomas not included in grade 1 with >15% of surface area with necrosis or ≥5 mitoses/10 high-power fields using a 40× objective

Modified from Parham DM, Webber BL, Jenkins JJ, III, et al: Nonrhabdomyosarcomatous soft tissue sarcomas of childhood: formulation of a simplified system for grading. Mod Pathol *8:705–710, 1995; and Khoury JD, Coffin CM, Spunt SL, et al: Grading of soft tissue sarcoma in children and adolescents.* Cancer *116:2266–2274, 2010.*

*Secondary criteria. Tumor diagnoses specified in grade 1 or 3 are excluded from grade 2.

TABLE 60-5 Surgical-Pathologic Grouping System of the Intergroup Rhabdomyosarcoma Study

Group	Definition
Low-Stage	
I	Localized disease, completely resected
II	Total gross resection with evidence of regional spread
IIa	Grossly resected tumor with microscopic residual disease
IIb	Regional disease with involved nodes, completely resected with no microscopic residual disease
IIc	Regional disease with involved nodes, grossly resected but with evidence of microscopic residual disease and/or histologic involvement of the most distal regional lymph node from the primary site in the dissection.
High-Stage	
III	Incomplete resection with gross residual disease
IV	Distant metastatic disease present at onset

Modified from Meza JL, Anderson J, Pappo AS, et al: Analysis of factors in patients with nonmetastatic rhabdomyosarcoma treated on Intergroup Rhabdomyosarcoma Studies III and IV: the Children's Oncology Group. J Clin Oncol *24:3844–3851, 2006.*

aggressively regardless of histologic appearance. To address these issues, the Pediatric Oncology Group (POG) grading system incorporates histology, cytologic features, and age to classify NRSTS as low, intermediate, or high grade (Table 60-4).[55] Low grade is defined by histologic type, whereas intermediate grade takes into account necrosis and mitosis with secondary consideration of nuclear atypia and tumor cellularity. High-grade tumors include those of specific histologies as well as tumors with more than 15% necrosis or five or more mitoses/10 high-power field. The National Cancer Institute (NCI) and Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading specifications are alternative methodologies validated on sarcomas in adults.[56-59] Similar to the POG system, they take into consideration mitotic index, necrosis, and histologic type or tumor differentiation. The POG and FNCLCC perform similarly in their ability to correlate with outcome.[60] Gene expression signatures have also been used to predict outcomes in non–translocation-associated sarcomas in adults.[61]

Pediatric multicenter studies also make use of the surgical-pathologic grouping system of the Intergroup Rhabdomyosarcoma Study (IRS) (Table 60-5), which incorporates tumor spread and outcome of surgical resection, or the International Society of Pediatric Oncology (SIOP)-International Union Against Cancer TNM classification system for pediatric tumors (Table 60-6).[62-64] STS may also be classified according to the American Joint Commission on Cancer (AJCC) or Enneking staging systems, which integrate tumor size, location relative to the superficial fascia, regional lymph node status, presence of distant metastases, and histologic grade (Table 60-7).[65,66]

NRSTS most commonly spread locally and hematogenously but may exhibit regional lymph node metastases. The lung is the most common site for distant metastases, but with less frequency these tumors can metastasize to

TABLE 60-6 SIOP-UICC TNM Soft Tissue Sarcoma Clinical Staging System

Stage	Description
I	T1—Tumor confined to organ or tissue of origin N0—No evidence of regional lymph node involvement M0—No evidence of distant metastasis
II	T2—Tumor involving one or more contiguous organs or tissues or with adjacent malignant effusion N0 M0
III	Any T N1—Evidence of regional lymph node involvement M0
IV	Any T Any N M1—Evidence of distant metastases

[*] Note: Superficial tumor is located exclusively above the superficial fascia without invasion of the fascia; deep tumor is located either exclusively beneath the superficial fascia, superficial to the fascia with invasion of or through the fascia, or both superficial yet beneath the fascia.

[†] Note: presence of positive nodes (N1) in M0 tumors is considered Stage III.

bone or brain. Metastatic spread at the time of diagnosis likely occurs in alveolar soft part sarcoma, high-grade MPNST, clear cell sarcoma, high-grade angiosarcoma, and epithelioid sarcoma.[5]

Several factors have been shown to be prognostic for tumor-associated mortality. In both univariate and multivariate analyses of patients with grossly resected tumors, tumor invasion into contiguous structures and size (>5 cm) are the most highly predictive of decreased 5-year event free survival (EFS) and overall survival (OS). Other factors that correlate with poor outcome including female sex, older age, high-grade tumors, high-grade MPNST histology, and tumors in nonextremity locations.[5]

TREATMENT

Surgical resection constitutes the mainstay of treatment of localized tumors. Complete resection for large tumors may result in significant functional compromise, and amputation should be considered for those patients in whom limb-sparing surgery would leave residual tumor. Radiation therapy is typically reserved for those tumors for which complete resection is not possible. However, the high radiation dose required for sarcoma therapy is associated with significant growth-associated side effects in children. Although surgery with or without radiation results in good outcome for localized and low-grade disease, high-grade disease is associated with significant morbidity and mortality. With the exception of synovial sarcoma and extraskeletal Ewing sarcoma, the role of conventional chemotherapy remains ill defined. However, in pediatric NRSTS, responses can be observed and may reduce tumor burden prior to surgical resection. Biologically targeted therapies have altered the management of individual tumor types (e.g., GISTs in adults), and their roles are evolving as they enter clinical trial.

Local Control

Surgical resection is typically the initial therapy for operable nonmetastatic NRSTS. Complete resection of small (<5 cm) NRSTS results in a 5-year OS in excess of 80%.[60,67-69,70] However, large, high-grade or incompletely resected tumors have a significant chance of local recurrence. Tumor location (e.g., abdomen vs. extremity) and invasion may limit the ability to perform a wide local excision necessary to achieve tumor-free margins. For these patients, external-beam radiation therapy has been used to reduce the risk for local recurrence based on adult studies.[71-73] Pediatric studies seem to confirm that radiation therapy reduces the risk for local recurrence associated with an inability to achieve a wide surgical margin (>1 cm) for high-grade disease.[74] The impact of postoperative radiation therapy may be most significant for IRS group II patients, although grade and size may mitigate this effect.[75] Higher radiation doses are associated with increased rates of local control in NRSTS.[76,77] However, these doses are associated with abnormalities of bone development, complicating the delivery of this modality to growing children.

Brachytherapy—interstitial, intercavitary or surface placement of radioisotopes—constitutes an alternative approach to deliver radiotherapy.[78,79] Brachytherapy can precisely deliver high doses of radiation to the tumor or resection site while sparing normal tissue. Brachytherapy can also be administered concurrently with external-beam radiation, and a study of adult STS suggests that the combination may result in increased rates of local control when surgical margins are positive.[80] Other techniques to augment local control include radiofrequency ablation, cryoablation, and embolization.[81-83] Strategies for local control that incorporate site-directed chemotherapy include intralesional chemotherapy followed by electroporation at accessible sites and intraperitoneal chemotherapy infusion.[84]

Chemotherapy

Because complete resection of NRSTS is associated with a high rate of cure, chemotherapy is principally employed when tumors are unresectable, incompletely resected, or metastatic. The infrequency of each of the heterogeneous tumors that constitute the class of NRSTS makes clinical trials of chemotherapy particularly challenging. To enable multicenter groups to accrue sufficient subjects, the nonselective inclusion of NRSTS complicates the interpretation and extrapolation of most trials. Nonetheless, several consistent themes emerge. In contrast to the striking successes of chemotherapy for Ewing sarcoma and rhabdomyosarcoma, NRSTS tend to be relatively chemoresistant, with synovial sarcoma and extraosseous Ewing sarcoma as exceptions.[5,69,85,86] For patients with fully resected tumors, the inclusion of chemotherapy fails to increase survival.[87,88] The impact of chemotherapy may be most significant for patients harboring tumors with the highest risk for metastatic spread. For high grade, grossly resected tumors, chemotherapy was associated with a 5-year metastasis-free survival of 49.5% compared with 0% for untreated patients.[89] Chemotherapy may also be beneficial for patients with unresectable tumors. For both chemotherapy-sensitive and chemotherapy-resistant tumors, neoadjuvant treatment may permit the subsequent surgical resection of initially nonresectable tumors.[85] Patients with unresected or metastatic tumors have a poor outcome, although 40% to 50% of patients with advanced disease demonstrate some response (partial + complete response) to a regimen containing either ifosfamide and doxorubicin or cyclophosphamide and doxorubicin.[86,88,90] Treatment with doxorubicin, cyclophosphamide, and vincristine alternating with ifosfamide and etoposide together with aggressive local control for incompletely resected tumors or those metastatic at presentation, resulted in a partial + complete response of 80%.[90] Approximately 40% of children and adolescents with NRSTS responded to ifosfamide and doxorubicin, results similar to those for cyclophosphamide and doxorubicin.[86,88] Based on the principle that advanced sarcomas may respond to intensive therapies, the feasibility of dose-intensified neoadjuvant chemotherapy has been an end point of several trials using doxorubicin, ifosfamide, and dacarbazine in adults and doxorubicin, cyclophosphamide, ifosfamide, etoposide, and vincristine in children.[86,91-94] However, evidence in support of high-dose chemotherapy with autologous stem cell infusion remains limited.[95]

Regarding specific chemotherapeutic agents, topoisomerase 1 inhibitors may also have activity against these tumors. Topotecan with high-dose cyclophosphamide as well as irinotecan demonstrated limited efficacy against recurrent NRSTS, and the effect of irinotecan together with temozolomide is currently being studied.[96-99] The combination of vinorelbine with low-dose cyclophosphamide may also have activity against these tumors.[100] Gemcitabine and docetaxel, both of which have some activity against adult sarcomas, were more effective together than gemcitabine alone in adult patients with metastatic sarcoma.[101] In adults, advanced disease may also respond to the combination of gemcitabine and vinorelbine.[102] In children, however, the efficacy of gemcitabine or docetaxel administered individually in the setting of relapsed pediatric solid tumors seems small.[103-105] As previously mentioned, synovial sarcoma is considered an exception to the general chemoresistance of NRSTS. Children and adolescents exhibit a 5-year EFS of about 70% with decreased EFS, progression-free survival (PFS), and OS associated with tumor size (>5 cm), local invasion, and IRS grouping (III and IV).[106-108,109] Another exception is extraosseous Ewing sarcoma, which is generally grouped with bony Ewing sarcoma for treatment purposes (see Chapter 61, "Ewing Sarcoma").

Insights regarding the biology of STS are beginning to identify novel targetable pathways. The management of GISTs in adults has been altered by treatment with KIT and PDGFR-targeted tyrosine kinase inhibitors. Multitargeted tyrosine kinase inhibitors have demonstrated efficacy in nonadipocytic STS in adults, and sorafenib has activity against desmoid tumors.[110,111] Insulin-like growth factor 1 (IGF-1) inhibition has demonstrated efficacy in a fraction of patients with DSRT.[112] Targeting the mammalian target of rapamycin (mTOR) pathway demonstrated a significant, although brief, delay in disease progression in a large adult trial of sarcomas previously treated with cytotoxic chemotherapy.[113]

GENERAL BIOLOGIC FEATURES

STS can be classified into two groups based on cytogenetics. Tumors that occur in children and young adults tend to reveal relatively simple karyotypes often characterized by an easily recognizable and frequently pathognomonic reciprocal chromosomal translocation. In contrast, STS of adults typically demonstrate complex karyotypes without recurrent cytogenetic abnormalities. Cellular mechanisms for telomere maintenance may correlate with translocation status. Tumors harboring single translocations tend to have normal to short telomeres, suggestive of active telomerase, whereas tumors with complex karyotypes have longer telomeres, suggesting the use of alternative mechanisms of telomere lengthening.[114-118] Although other cellular changes, in addition to translocations, are likely to be necessary for sarcoma development, the difference between sarcomas of children and young adults and those of older individuals may reflect divergent cellular origins. Experimentally, haploinsufficiency of the nonhomologous end-joining DNA repair pathway in the context of *Ink4a/Arf*-deficient mice leads to the development of sarcoma with varied histology and karyotype.[119] Although the tumors that develop in these mice demonstrate translocations, amplifications, and deletions, the translocated regions are not recognizably syntenic with known human translocations suggesting that these sarcomas more closely reflect adult sarcomas. This finding also highlights the issue of whether complex cytogenetic abnormalities themselves result in oncogenesis or are a manifestation of genomic instability associated with the loss of cell cycle and DNA repair checkpoints.

ADIPOCYTIC TUMORS

Liposarcoma is the most common of the STS in adults.[120] In children, however, approximately 95% of adipose tumors are benign lipomas and lipoblastomas with liposarcomas accounting for the remainder.[121] Lipoblastomas tend to occur in children younger than 3 years of age, whereas liposarcomas predominate in older school-aged children and adolescents. Liposarcoma is classified into three morphologic types: well-differentiated/dedifferentiated, myxoid/round cell, and pleomorphic.[122] Morphologic types correspond to a developmental progression bearing similarities to that seen during induced mesenchymal differentiation into adipocytes.[123] Dedifferentiated/well-differentiated and pleomorphic liposarcomas occur predominantly in the retroperitoneum, whereas myxoid/round cell histology tends to occur in the extremities.[124] High-grade, dedifferentiated liposarcomas carry the highest risk for recurrence and metastasis.[125,126] In contrast to adults, most children present with the myxoid variant.[127,128] Myxoid liposarcoma is histopathologically characterized by proliferation of round to spindled primitive mesenchymal cells and scattered lipoblasts in an abundant faintly eosinophilic, homogeneous myxoid matrix (Fig. 60-2). A network of delicate straight and curvilinear capillaries is distinctive. The presence of a round cell component may increase the risk for disease progression.[129] Complete resection is associated with prolonged tumor-free survival. When margins are microscopically positive, the addition of radiation therapy may increase disease-free survival. The histologic variants of liposarcoma are associated with differences in response to chemotherapy. Myxoid liposarcoma demonstrates the highest likelihood of response to a doxorubicin and ifosfamide regimen.[130] Myxoid liposarcoma also exhibits sensitivity to trabectedin (ecteinascidin-743; ET-743), a DNA minor groove–binding small molecule.[131,132]

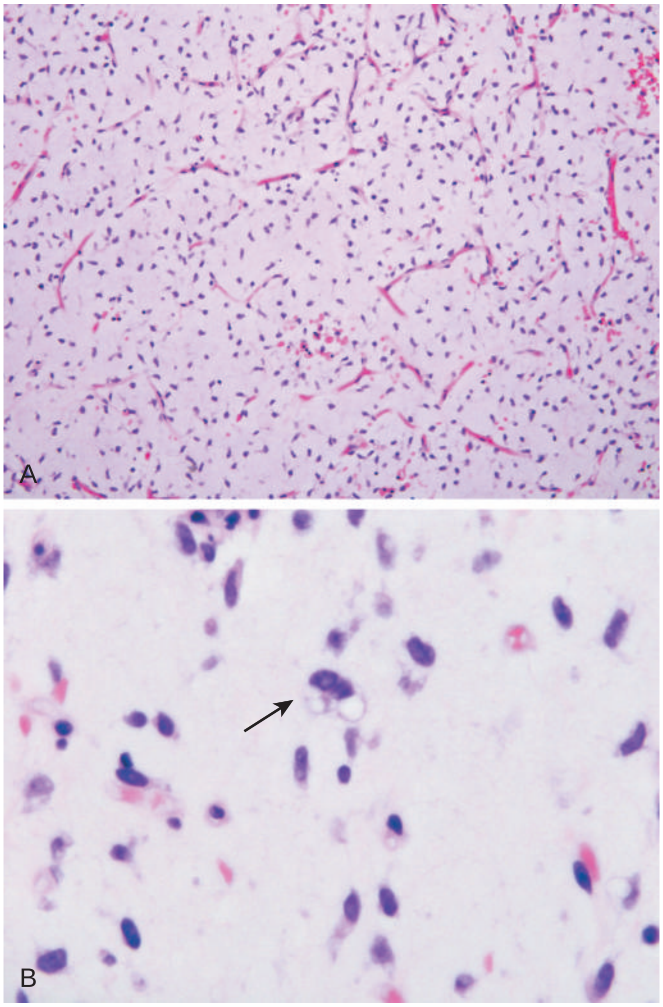

Figure 60-2 Myxoid liposarcoma. **A,** Uniform stellate and spindled cells in a prominent myxoid stroma and with characteristic branching capillaries. **B,** Primitive tumor cells and scattered lipoblasts *(arrow)* in a myxoid background.

Myxoid and round cell liposarcomas share recurrent chromosomal translocations that distinguish them from other liposarcoma histologies. t(12;16)(q13;p11) results in fusion of *FUS* (also known as TLS, an abbreviation for translocated in liposarcoma) with the transcription factor *DDIT3 (CHOP)*, and t(12;22)(q13;q11) fuses *EWSR1* with *DDIT3*.[133-135] DDIT3 is a member of the b-ZIP family of transcriptional regulatory proteins and seems to function as a negative transcriptional regulator. Chimerism with both EWSR1 and FUS (TLS) suggests that the retained domains of EWSR1 and FUS confer similar activities to the DNA-binding domain of *DDIT3*. Ectopic expression of either FUS-DDIT3 or EWSR1-DDIT3 in NIH-3T3 cells resulted in characteristics of oncogenic transformation, including growth in soft agar and tumor formation in immunocompromised mice.[136] Furthermore, implantation of mice with primary murine mesenchymal progenitor cells transduced with FUS-DDIT3 led to the development of tumors that morphologically and immunohistochemically resemble human myxoid liposarcoma.[137]

Well-dedifferentiated liposarcomas are associated with complex karyotypes. However, a frequent finding is amplification of 12q, which includes *MDM2* and *CDK4*.[138,139] MDM2 binds TP53 to inhibit its activity. In the context of wild-type *TP53*, inhibition of MDM2 by the small molecule nutlin3 results in increased apoptosis in liposarcoma cell lines.[140,141] Transgenic mice expressing FUS-DDIT3 in mesenchymal progenitor cells developed sarcomas only in the absence of TP53. Interestingly, treatment of these mice with trabectidin resulted in adipocytic differentiation, which was increased by concurrent treatment with the peroxisome proliferator-activated receptor γ (PPARγ) agonist rosiglitazone.[142] Comprehensive genomic analysis of several sarcomas demonstrated *TP53* and *NF1* mutation in a subset of pleomorphic liposarcomas whereas *PIK3CA* was mutated in nearly 20% of myxoid/round cell liposarcomas.[143]

Chromosomal rearrangements of 8q12 are found in lipoblastoma, and their detection can aid in diagnosis. These rearrangements have implicated the zinc finger DNA-binding protein PLAG1. In lipoblastoma, translocation places the PLAG1 coding exons under the transcriptional control of the *HAS2, COL1A2,* or *RAD51L1* promoters.[144,145] PLAG1 was originally identified based on its translocation in pleomorphic adenoma of the salivary gland.[146] In contrast to lipoblastoma, *PLAG1* is translocated near *CTNNB1, CHCHD7* or *TCEA1* in pleomorphic adenoma.

FIBROBLASTIC AND MYOFIBROBLASTIC TUMORS

Desmoid Tumor

Desmoid tumor, also known as deep musculoaponeurotic fibromatosis, presents from infancy through adulthood with a median age at diagnosis in the early 30s and a twofold higher incidence in women. Although most tumors occur spontaneously, FAP patients, and in particular those with Gardner syndrome, have reported incidences of desmoid tumors ranging from 3.5% to 32%.[27,147] Desmoid tumors in the pediatric population tend to occur in the second decade and are located in the extremities and head and neck, in contrast to the adult population in whom abdominal and truncal sites are common.[148,149] Abdominal desmoids are more common in FAP patients, whereas limb and trunk locations predominate in non-FAP patients.[150]

The tumors consist of an infiltrating, uniform, spindled cell proliferation lacking nuclear pleomorphism and mitotic activity (Fig. 60-3). Although desmoid tumors have a high potential for local invasion and recurrence, they never metastasize. Surgery is the primary treatment; however, tumors have a significant chance of local recurrence even if negative margins can be achieved.[149] Achieving negative margins without severe disfigurement or functional impairment may be impossible. In these circumstances, preoperative chemotherapy or partial resection and postoperative chemotherapy should be considered, although, given a highly variable clinical course, close observation may be justified. Multiple drug regimens have been shown to shrink or stabilize desmoid tumor growth. These include methotrexate with vinblastine or tamoxifen with diclofenac.[151-154] Other potentially active treatments include the combination of doxorubicin, vincristine, dactinomycin, and cyclophosphamide or the combination of doxorubicin and dacarbazine.[155-157] Responses to imatinib and sorafenib have been observed in about half of desmoid patients.[111,158,159]

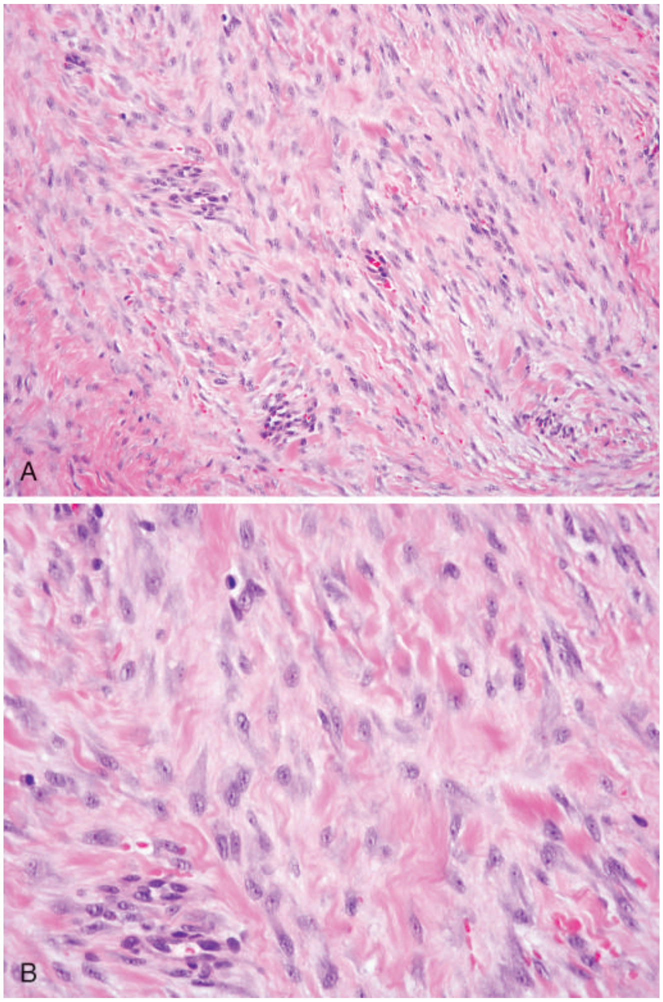

Figure 60-3 Desmoid tumor. **A,** Spindle cell neoplasm with prominent collagenization. **B,** Tumor cells are histopathologically bland with ovoid uniform nuclei, open chromatin, and single small nucleolus. Some cells have abundant eosinophilic cytoplasm.

Although most desmoid tumor cells are karyotypically diploid, abnormalities of the Y chromosome and 5q and gains in chromosome 8 and 20 may be noted.[160-163] Abnormalities have been identified in a subset of tumor cells, and the finding of trisomy 8 may suggest an increased risk for recurrence.[161] Gardner syndrome, which is associated with colonic polyposis and abdominal desmoid tumors, is a phenotypic variant of FAP, which is caused by mutation of *APC*. APC regulates β-catenin, the downstream mediator of WNT signaling. Stabilized β-catenin forms a multiprotein complex with members of the T-cell factor/lymphoid enhancer factor family (TCF-LEF) resulting in transcriptional activation of TCF-LEF target genes.[164-167] *APC* mutations resulting in increased β-catenin or stabilizing mutations in the β-catenin gene (*CTNNB1)* have been implicated in the proliferation of sporadic desmoid tumors.[168-170] Eighty-five to 90 percent of sporadic desmoid tumors are associated with somatic mutation of *CTNNB1*.[171] Mice expressing either mutant *APC* or stabilized β-catenin develop aggressive fibromatoses.[172,173]

Infantile Myofibroma/Myofibromatosis and Hemangiopericytoma

In recent World Health Organization (WHO) classifications of soft tissue tumors, the term *hemangiopericytoma* is no longer used; instead, a majority of these tumors are currently classified as solitary fibrous tumors.[174,175] Infantile hemangiopericytoma, recognized as a distinct category of benign hemangiopericytoma by Enzinger, is currently regarded in the category of infantile myofibroma/myofibromatosis.[176] Infantile myofibromatosis is a benign proliferation of myofibroblastic cells affecting almost exclusively young children. The tumors are solitary or multicentric and may involve the skin, muscle, viscera, or bone. Sixty percent are noted at birth, and 88% occur before the age of 2.[177] More commonly found in males, solitary lesions typically develop in the soft tissues of the head and neck and trunk. In contrast, the multicentric form is more common in females and in addition to affecting soft tissues it can develop in bones and viscera. Histopathologically, infantile myofibroma and myofibromatosis have similar features. They are multinodular and biphasic with alternating hemangiopericytoma-like,

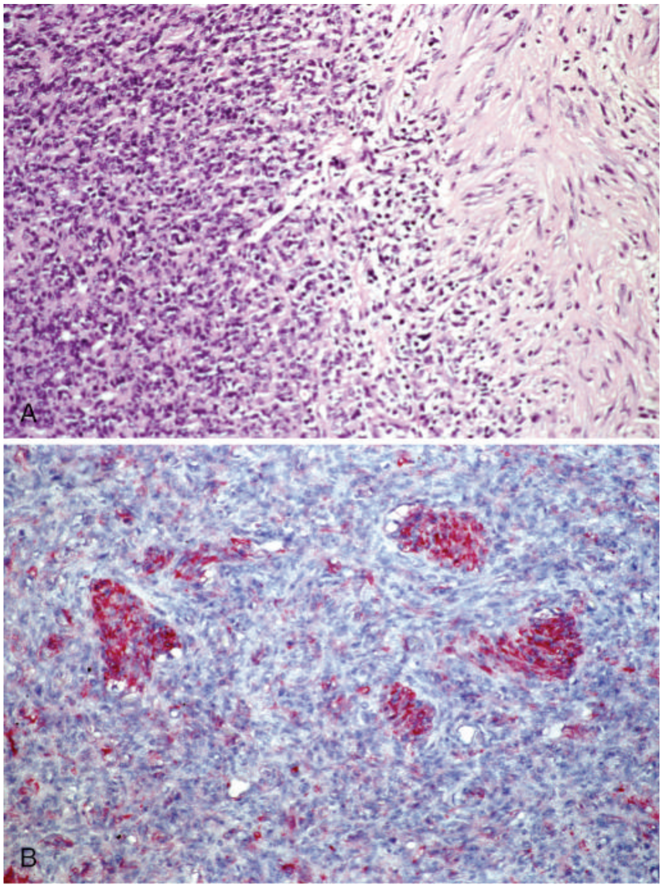

Figure 60-4 Infantile myofibromatoses. **A**, Biphasic tumor with an area of bland smooth musclelike proliferation *(right)* sharply demarcated from an area of cellular hemangiopericytoma-like tumor. **B**, Characteristic nests of strongly actin-immunoreactive cells *(red)* are scattered through a cellular hemangiopericytoma-like area.

densely cellular areas and less cellular areas with smooth muscle differentiation immunoreactive to actin (Fig. 60-4). Solitary lesions can rarely recur. Multicentric lesions undergo spontaneous regression; however, multiple visceral lesions may increase in size and number prior to regression, compromising vital structures and, rarely, leading to death.[178] Optimal initial therapy involves complete surgical excision. Life-threatening multifocal disease has been treated successfully with low-dose vincristine and dactinomycin or low-dose vinblastine and methotrexate.[179] Urinary basic fibroblast growth factor has been shown to be elevated in an infant during the proliferative phase, and connective tissue growth factor is expressed in both tumor and stromal cells.[180,181] An autosomal dominant pattern of inheritance has been associated with mutations in the growth factor receptor PDGFRB.[182-186]

Infantile myofibroma/myofibromatosis should be distinguished from pericytoma with t(7;12), a distinct tumor with histologic, immunohistochemical, and ultrastructural features of pericytic differentiation and a translocation involving t(7;12)(p22;q13).[187] Although typically developing in soft tissue, this entity can develop in bone.[188] The translocation brings together the β-actin gene *(ACTB)* with the zinc finger transcription factor *GLI1*.[189] Originally identified based on amplification in human glioma, GLI1 is activated by Sonic hedgehog signaling through the transmembrane receptor *PTCH*.[190-192] In t(7;12) pericytoma the carboxyl terminus of GLI1 is fused with the amino-terminal domain of ACTB. Intriguingly, *GLI1* has also been found to be amplified in a subset of rhabdomyosarcoma and osteosarcoma that lack typical markers of differentiation.[193]

Infantile Fibrosarcoma

Infantile (congenital) fibrosarcoma is one of the most common NRSTS in young children.[194] In contrast to fibrosarcoma in adults, this low-grade tumor displays a benign clinical behavior and is typically cured by surgical excision. However, large tumors for which surgical excision would result in significant morbidity may be treated with preoperative chemotherapy (Fig. 60-5, *A*). Regimens with activity against these tumors include vincristine and dactinomycin alone or together with either cyclophosphamide, ifosfamide, or doxorubicin.[195-202]

Histopathologically, the tumor is characterized by intersecting bundles with a herringbone pattern composed of cellular spindle to ovoid cells with a high proliferative rate, frequent mitoses, and areas of necrosis (see Fig. 60-5, *B* and *C*). Some tumors may have a hemangiopericytoma-like pattern of growth. Scattered chronic inflammatory cells are frequently present. Tumor cells have a fibroblastic and myofibroblastic ultrastructure (see Fig. 60-5, *D*) and immunophenotype with variable positivity for desmin and actin. Aberrant cytokeratin expression is observed in 15% to 20% of the tumors.

Infantile fibrosarcoma is characterized by t(12;15)(p13;q25).[203] This translocation fuses the amino-terminal helix-loop-helix oligomerization domain of the ETV6 transcription factor (also known as *TEL*) with the carboxyl-terminal tyrosine kinase domain of the neurotrophic tyrosine kinase receptor, type 3 (*NTRK3*, also known as *TRKC*). The detection of ETV6-NTRK3 by reverse-transcriptase PCR is highly specific and can distinguish infantile fibrosarcoma from more aggressive spindle cell sarcomas.[204] Intriguingly, the same translocation also occurs in congenital mesoblastic nephroma, secretory breast carcinoma, and acute myeloid leukemia.[205-208]

Chimerism results in constitutive activation by autophosphorylation of NTRK3 tyrosine residues. Translocation also results in aberrant *NTRK3* expression. *ETV6* is widely expressed whereas *NTRK3* is normally restricted to neuronal cells and fetal kidney.[209-211] ETV6-NTRK3 expression can transform NIH3T3 cells as assayed by growth in soft agar and in xenografts in immunocompromised mice.[212] ETV6-NTRK3 is associated with several signaling pathways that may be important in oncogenesis. ETV6-NTRK3 activates both the MAPK and AKT pathways, with AKT activation mediated by direct interaction of ETV6-NTRK3 with SRC.[213,214] Activation of signaling also leads to phosphorylation of YAP1 and WWTR1, Hippo pathway transcriptional coactivators, and a characteristic transcriptional profile.[215] ETV6-NTRK3–mediated fibroblast transformation also requires the insulin-like growth factor receptor (IGF1R) possibly

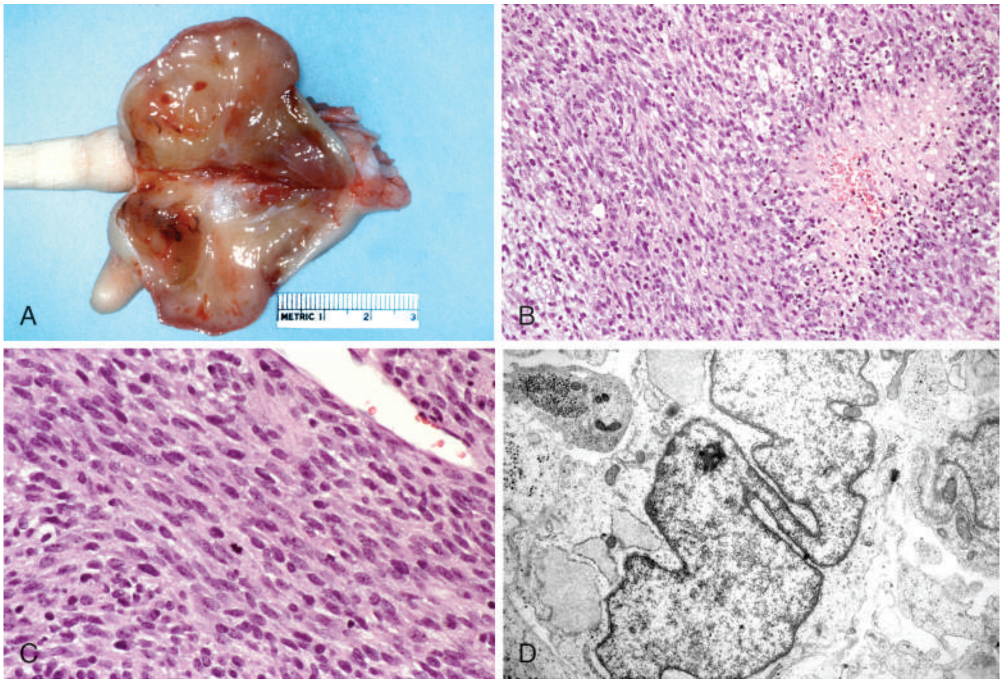

Figure 60-5 Infantile fibrosarcoma. **A,** Partial amputation of the hand in an infant with a rapidly growing soft tissue mass. On cut section the mass is fleshy and soft with areas of hemorrhage and necrosis. **B,** Histopathology shows a cellular spindle cell sarcoma with frequent mitoses, apoptosis, and confluent areas of necrosis. **C,** At higher magnification, nuclei appear uniform and hyperchromatic and cytoplasm is elongated and pink. Scattered inflammatory cells are also present. **D,** Ultrastructurally, tumor cells have the features of fibroblasts with prominent secretory-type rough endoplasmic reticulum.

through directly interacting with the IGF1R substrate IRS-1.[216-218] The ETV6-NTRK3 fusion may also act by suppressing transforming growth factor-β (TGF-β) signaling through interaction with the type II TGF-β receptor.[219]

Fibrosarcoma Arising in Dermatofibrosarcoma Protuberans and Giant Cell Fibroblastoma

Dermatofibrosarcoma protuberans (DFSP) is a rare cutaneous fibrohistiocytic tumor characterized by locally aggressive behavior. DFSP may begin as a plaquelike, raised red-blue lesion followed by a rapid growth phase that may be associated with the development of one or more nodules. DFSP appears as a cellular, spindle cell proliferation, frequently with a distinct storiform pattern that infiltrates the surrounding dermis and subcutaneous fat (Fig. 60-6, *A*). Tumor cells are typically immunoreactive for apolipoprotein D and CD34 (see Fig. 60-6, *B*). The Bednar tumor refers to an uncommon DFSP variant with scattered dendritic cells containing melanin.[220] The majority of the tumors develop on the trunk and upper extremity. Although typically diagnosed during the fourth and fifth decades, DFSP may occur in children and adolescents.[221] Inadequate resection of the tumor is associated with a significant risk for local recurrence.[222] Radiation therapy can be used effectively as an adjuvant for the treatment of resection sites with positive margins.[223-225] Rarely, DFSP can evolve into a high-grade fibrosarcoma often associated with a loss of CD34 staining and an increased risk for metastasis (Fig. 60-7, *A* and *B*).[226] Giant cell fibroblastoma, a rare tumor predominantly of males younger than 10 years of age, is in the spectrum of DFSP. Histopathologically, giant cell fibroblastoma is composed of variably cellular spindle or stellate cells often in a myxoid background containing pseudovascular spaces and multinucleated giant cells (see Fig. 60-7, *C*).[227-229]

Like DFSP, giant cell fibroblastoma is characteristically immunoreactive for CD34 and apolipoprotein D.[230] Both lesions also harbor a pathognomonic translocation between the collagen, type I, alpha 1, gene *(COL1A1)* and the platelet-derived growth factor-β gene *(PDGFB)*.[231-233] In contrast to the other sarcoma-associated translocations, the translocated *COL1A1-PDGFB* locus may be present as a low-level amplification on a ring chromosome. Detection of the resulting *COL1A1-PDGFB* transcript can provide confirmation of the diagnosis.[234] The fusion of *PDGFB* with *COL1A1* preserves the full coding region of *PDGFB,* and the resulting chimeric polypeptide is subject to intracellular processing that results in the secretion of a native PDGFB molecule that is capable of activating its receptor, PDGFR.[235,236] Although the mechanisms for autocrine-activated PDGFR signaling are not known, it may function through STAT3 and ERK activation.[237] Presumably through the inhibition of autocrine PDGFR activation, the growth of xenografted primary human DFSP cells can be inhibited with the kinase inhibitor imatinib (Gleevec).[238] Treatment with imatinib has also been shown to be effective in children and in patients with metastatic or unresectable disease.[239-245] Imatinib-resistant DFSP may respond to sorafenib or sunitinib.[246,247] Response to vinblastine and methotrexate has also been reported.[248]

Low-Grade Fibromyxoid Sarcoma

Low-grade fibromyxoid sarcoma (LGFMS) typically develops in the lower extremities of young adults and occasionally in adolescents (Fig. 60-8). Described by Evans in 1987, it is characterized by bland, uniform spindle cells with a short fascicular or whorly pattern of growth in a dense collagenous or variably myxoid stroma (Fig. 60-9).[249,250] An abrupt transition between cellular myxoid and hypocellular collagenous areas is frequently present. Dense collagenous areas mimic desmoid tumor. Myxoid areas contain characteristic arcades of curvilinear vessels that may be sclerotic or be surrounded by more densely cellular spindle cells. Mitotic count is characteristically low. Occasionally there are giant collagenous rosettes (hyalinizing spindle cell tumor with giant rosettes). Vimentin is the only constant marker present in tumor cells. Some tumors may be focally immunoreactive for actin, CD34, cytokeratins, or epithelial membrane antigen (EMA). MUC4 reactivity is common in LGFMS and can distinguish it from other histologically similar tumors.[251] A superficial location occurs more frequently in children.[252] Although primary resection typically results in disease control, local recurrences and pulmonary metastases can develop in 5% to 10% of patients after many years.[253,254] However, resection of recurrent disease can result in long-term remission. LGFMS seems to be chemoresistant, although limited responses to trabectedin have been reported.[255,256]

LGFMS is associated with t(7;16)(q34;p11) or t(11;16)(p11;p11), which results in the fusion of *FUS (TLS)* with *CREB3L2* or *CREB3L1*.[257-260] These translocations are also found in sclerosing epithelioid fibrosarcoma, suggesting that these tumors may be related.[261] *EWSR1-CREB3L1* has also been noted.[262] Native CREB3L2 is a member of the CREB basic leucine zipper family of transcription factors and acts as a transducer of endoplasmic reticulum (ER) stress signals. Normally tethered through a transmembrane domain to the ER, ER stress results in cleavage of the cytoplasmic amino terminal b-ZIP domain, enabling it to translocate to the nucleus and to activate

transcription from cyclic adenosine monophosphate (AMP)–responsive elements.[263] Chimerism with FUS, a translocation partner with CHOP in myxoid liposarcoma, likely deregulates CREB3L2 transcriptional activity.[264] PCR-based identification of the fusion gene product from paraffin sections can be used to confirm the diagnosis.[261] LGFMS is associated with a gene expression profile that distinguishes it from similar tumors and is marked by the expression of *FOXL1*.[265]

Myxofibrosarcoma

Myxofibrosarcoma (MFS) is one of the most common sarcomas of the elderly but has been reported in adolescents and young adults.[266,267] Typically developing in the sixth and seventh decades of life, MFS exhibits a predilection for the dermal or subcutaneous tissues of the extremities.[268-270] MFS may be alternatively referred to as low-grade myxoid malignant fibrous histiocytoma or fibrosarcoma, myxoid type. Histopathologically, it is characterized by a multinodular growth of spindled or stellate cells in a myxoid stroma (Fig. 60-10). MFS grading has prognostic value and is based on cellularity, nuclear pleomorphism, and mitotic activity.[271] Resection is typically curative for low- or intermediate-grade tumors; however, recurrent tumors may show morphologic and molecular multistep tumor progression.[272,273] Large tumor size, necrosis, and decreased myxoid stroma in low-grade tumors are associated with a significant risk for local and distant recurrence.[274] Intermediate- and high-grade tumors have a significant risk for recurrence and metastasis.[275] In a study of adults, 23% of patients with intermediate- or high-grade tumors developed metastases, most commonly to the lung and lymph nodes and rarely to the brain. A subset of intermediate- or high-grade tumors exhibiting an epithelioid morphology seems to behave more aggressively than other high-grade histologies.[276] In addition to grade, an initial incomplete resection and infiltrative MRI T2-weighted signal

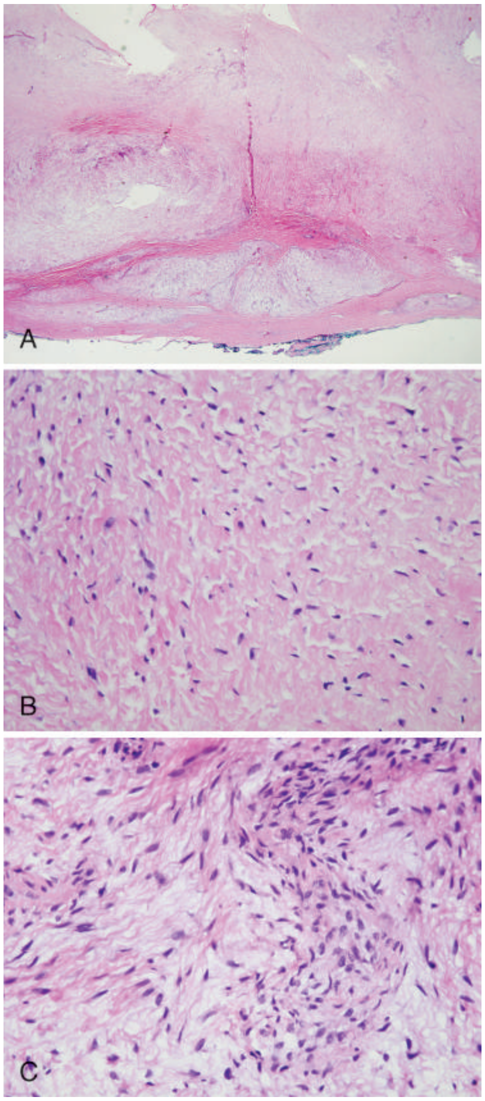

Figure 60-9 Low-grade fibromyxoid sarcoma. **A,** Multinodular, infiltrative growth at the tumor periphery and a variably myxoid stroma. **B,** Fibromatosis-like area with bland spindled cells immersed in a collagenous background. **C,** Characteristic curvilinear blood vessels, bland spindled cells, and myxoid background.

correlates with an increased risk for local recurrence.[277] Combined chemotherapy and irradiation has efficacy for MFS.[278] Cytogenetically, MFS may be diploid but is typically complex. Numerous chromosomal gains and losses as well as ring chromosomes have been observed.[273,279] Large-scale 7q gains were associated with increased expression of the hepatocyte growth factor receptor MET and CDK6, and increased expressed of these proteins was associated with lower metastasis-free survival.[280,281] Ezrin expression also correlates with decreased metastasis-free survival.[282] Isolated chromosomal translocations have been noted.[283,284]

Solitary Fibrous Tumor

Solitary fibrous tumor (SFT) is a fibroblastic tumor that was originally described in the pleura but can occur at other sites, most frequently the abdomen and pelvis. Most of the tumors formerly classified as hemangiopericytomas are currently categorized as SFT. SFT can be classified as classic, malignant, or dedifferentiated.[285,286] Five to 10 percent of soft tissue SFTs are malignant. SFT may be associated with hypoglycemia owing to synthesis by tumor cells of insulin-like growth factor 2 (IGF-2).[287,288] The histopathology is described as a patternless proliferation of spindle cells with a hemangiopericytoma-like growth (Fig. 60-11). Areas of sclerosis and hyalinization are characteristic. Mitotic count is generally low. Although the behavior of SFTs cannot be always predicted by histopathology, the presence of frequent mitoses, hypercellularity, pleomorphism, and necrosis is generally associated with malignant behavior. Large tumors and those with a mitotic index greater than 4 indicate an increased risk for recurrence locally or, more frequently, metastatically, even in the presence of negative resection margins.[289] Tumor cells are immunoreactive with CD34 and CD99 (see Fig. 60-11, *inset*). Some tumors also express EMA, actin, BCL2, apolipoprotein D, or nuclear β-catenin.[290-292] Recurrent NAB2-STAT6 fusions have

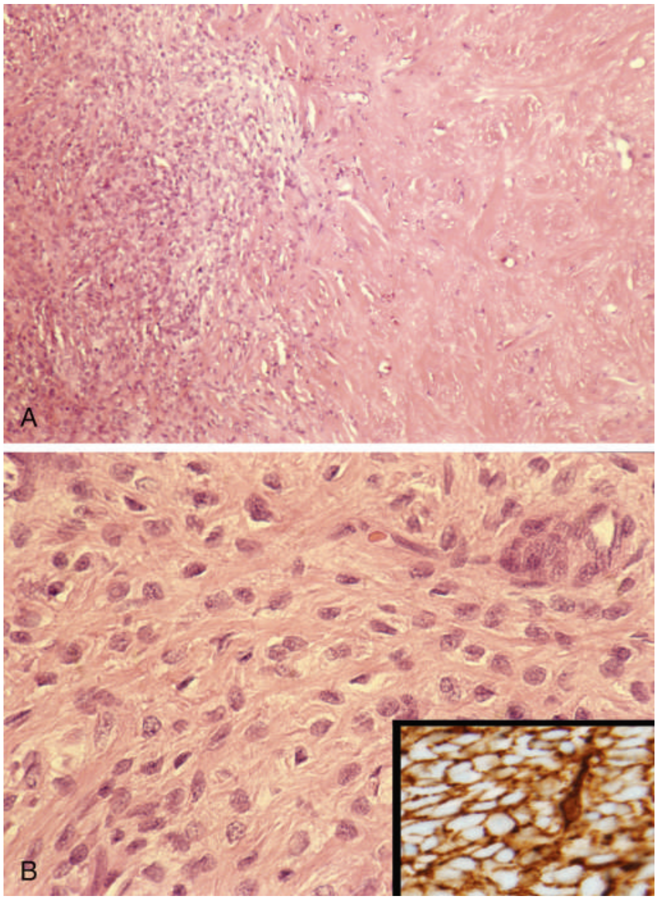

Figure 60-11 Solitary fibrous tumor. **A,** Spindle cell tumor with a prominent area of sclerosis. **B,** Patternless proliferation of spindled cells with uniform, ovoid nuclei, inconspicuous nucleoli, and eosinophilic cytoplasm with poorly defined borders. Tumor cells are strongly immunoreactive with CD34 *(inset)*.

been identified in the majority of SFTs regardless of the site of origin or SFT classification.[293,294] In this fusion protein, NAB2 contributes an amino-terminal EGR1 binding domain and STAT6 contributes a carboxyl terminal transcriptional activation domain with or without an associated DNA-binding domain. The resulting protein may cooperate with EGR1 to activate growth factor pathways. Based on this chromosomal rearrangement, virtually all SFTs demonstrate nuclear expression of STAT6 by immunohistochemistry.[295] Dacarbazine has demonstrated efficacy in SFTs as has treatment with bevacizumab or one of several tyrosine kinase inhibitors, including sorafenib, sunitinib, and pazopanib.[110,296-300]

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMTs) occur primarily in the viscera and soft tissue (particularly lungs) of children and young adults with a mean age of 13.2 years.[301] Of intermediate biologic potential, these tumors often recur locally but rarely metastasize. They are characterized by a proliferation of myofibroblastic spindled cells and an inflammatory, predominantly lymphoplasmacytic infiltrate (Fig. 60-12, *A*). Approximately half of IMTs show immunoreactivity for anaplastic lymphoma kinase (ALK) (see Fig. 60-12, *B*). ALK-positive IMTs are more common in younger patients and seem less likely to metastasize than ALK-negative disease, although local recurrence occurs with equal frequency.[301]

Clonal cytogenetic changes that activate ALK occur in 50% to 70% of IMTs.[302] The most common chromosomal translocation results in a fusion of the *ALK* receptor tyrosine kinase with the amino-terminal coiled domain of tropomyosin 3 or tropomyosin 4 (*TPM3* and *TPM4*). ALK may also be fused to the amino-terminal domains of clathrin heavy chain *(CTLC)*, cysteinyl-tRNA synthetase, RAN-binding protein 2 *(RANBP-2), SEC31L1,* or *PPFIBP1.*[303-307] ALK rearrangements were first identified in anaplastic large cell lymphoma, in which the fusion of *ALK* with nucleophosmin is most common, although chimerism with *CTLC* has also been observed.[308,309] Possibly based on ALK hyperactivation, the ALK/MET inhibitor crizotinib has demonstrated activity, although the response may be limited by mutation-associated resistance.[310-312] IMTs frequently demonstrate expression of MYC, cyclin D1, and MCL1 regardless of ALK status. Cyclooxygenase 2 inhibitors may be effective for IMT.[313,314]

SO-CALLED FIBROHISTIOCYTIC TUMORS

Plexiform Fibrohistiocytic Tumor

Plexiform fibrohistiocytic tumor is a fibrohistiocytic neoplasm of intermediate malignant potential with a multinodular (plexiform) pattern of growth that occurs in the deep dermis and subcutaneous tissue primarily in children, adolescents, and young adults, with a mean age of 14.5 years.[315,316] Histopathologically these tumors are characterized by a plexiform growth of small nodules composed of mononuclear histiocyte-like cells, fibroblasts, and multinucleate giant cells (Fig. 60-13). Mitoses are infrequent, and pleomorphism is minimal. Immunohistochemical findings reflect the proportion of histiocytic to fibrous elements, with CD68 marking osteoclast-like multinucleated giant cells and smooth muscle actin (SMA) focally marking the fibrous component.[317] These tumors are histologically similar to some neurothekomas, but immunohistochemical staining for microphthalmia-associated transcription factor (MITF) may discriminate these entities.[318,319] This tumor has a tendency to locally recur and in about 5% of cases may metastasize, particularly to regional lymph nodes.[320] Cytogenetic abnormalities in the few cases reported are heterogeneous.

SMOOTH MUSCLE TUMORS

Sporadic Leiomyosarcoma

Leiomyosarcoma (LMS) is one of the most common STS in adults.[321] LMS can develop in uterus, bowel, vascular structures, and skin, as well as soft tissue and bone.[322,323] In children, LMS most commonly develops in the gastrointestinal tract and skin. In infants, intestinal LMS can present as perforation and obstruction.[324,325] In the head and neck, trunk, and extremities LMS has an equal incidence and tends to exhibit a more low-grade morphology and a clinical behavior comparable to that in adults.[326,327] Secondary LMS may develop in the radiation field of childhood cancer survivors.[328] Histopathologically, LMS is characterized by intersecting fascicles of spindle cells with prominently eosinophilic cytoplasm and elongated cigar-shaped nuclei (Fig. 60-14). In some tumors, nuclear pleomorphism and hyperchromatism are present. Mitoses are usually easily found, and their frequency is often uneven throughout the tumor. Tumor cells are immunoreactive for SMA, desmin, and h-caldesmon.

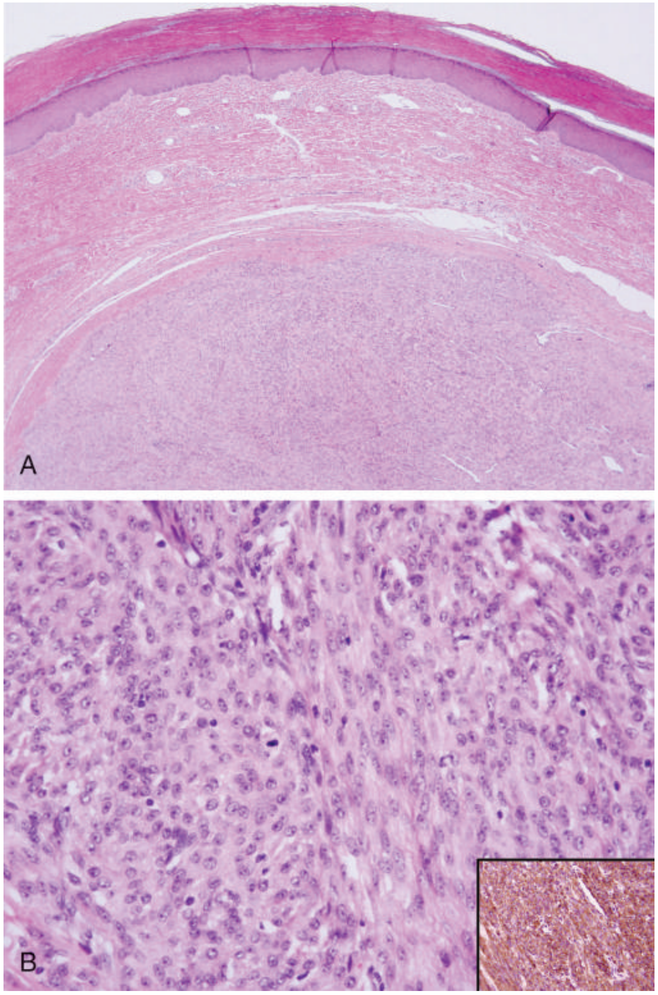

Figure 60-14 Leiomyosarcoma. **A,** Large tumor nodule is centered in the deep dermis and subcutaneous tissue. **B,** Tumor cells are spindled and have brightly eosinophilic cytoplasm and prominent nuclei with distinct centrally located nucleoli. Note strong and diffuse immunoreactivity for smooth muscle actin *(inset).*

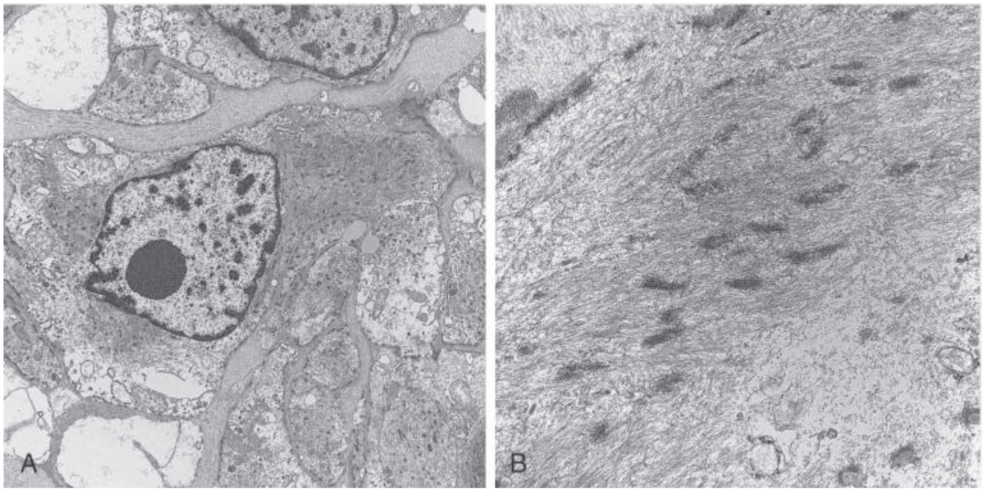

Figure 60-15 Leiomyosarcoma, electron microscopy. **A,** Tumor cells are individually invested by a continuous, well-developed basal lamina, and the abundant cytoplasm is filled with smooth muscle–type filaments. **B,** At higher magnification, note actin-type filaments with uniformly distributed dense bodies, typical of smooth muscle.

Ultrastructurally, tumor cells are invested by a continuous basal lamina and have subplasmalemmal densities and their cytoplasms contain abundant smooth muscle–type myofilaments with evenly distributed dense bodies (Fig. 60-15). Owing to the morphologic continuum of smooth muscle tumors, mitotic activity is the most reliable way to distinguish a leiomyoma from an LMS.

LMS has been treated with doxorubicin or ifosfamide as a single agent but with limited efficacy.[329,330] Patients with unresectable LMS treated with gemcitabine together with docetaxel demonstrated an overall response rate of 53%.[331] In recurrent or progressive STS, including LMS, the combination of gemcitabine and docetaxel was superior to gemcitabine alone.[101] Gemcitabine with docetaxel followed by doxorubicin in uterus-limited LMS resulted in a 57% PFS at 3 years.[332] When vinorelbine or dacarbazine is combined with gemcitabine the response rates have been reported as 15% to 20%.[102,333] Treatment with bendamustine resulted in stable disease in 40% of patients with LMS refractory to other agents.[334] Treatment with trabectedin is associated with disease stabilization in a significant fraction of patients in several clinical trials, including in pretreated LMS patients.[132,335-338] The multikinase inhibitor pazopanib also has limited disease-stabilizing activity in LMS.[110,339]

Germline mutation of the fumarate hydratase gene *(FH),* resulting in fumarate hydratase deficiency, is associated with a cancer predisposition syndrome with an increased risk for renal cell carcinoma, benign leiomyomas of the skin and uterus, and uterine leiomyosarcoma.[340,341,342] These tumors exhibit complex and unbalanced karyotypes. Genome-wide examination of DNA copy number variation and gene expression segregates a class enriched in the conventional LMS histologic subtypes with chromosome 10 and 13 losses and gains at 17p11-12. The remainder exhibit gene expression and copy number variation patterns similar to those of undifferentiated pleomorphic sarcomas and MFS.[343,344] *MED12,* which is mutated in the majority of uterine leiomyomas, is occasionally mutated in leiomyosarcoma.[345,346] MED12 is a component of the mediator transcriptional complex and can regulate TGF-β receptor signaling, influencing cellular responses to tyrosine kinase inhibition.[347] Vascular endothelial growth factor (VEGF) overexpression detected by immunohistochemistry was associated with a significantly shorter survival, suggesting a mechanism for the activity of pazopanib.[348] Tissue and expression microarray-based studies comparing uterine LMS with uterine leiomyoma demonstrated increased expression of CDKN1A, TP53, PDGFR, KIT, and CDKN21A.[349-354] Approximately 20% of transgenic mice expressing teratocarcinoma-derived growth factor 1 (also known as CRIPTO) from an MMTV promoter developed uterine leiomyosarcoma.[355,356] Chromosome 10q deletion is associated with *PTEN* loss and hyperactivation of the phosphatidylinositol 3′-kinase/serine–threonine kinase (PI3K/AKT) pathway. Consistent with the importance of this pathway in LMS, conditional *Pten* inactivation in smooth muscle led to the development of abdominal LMS in mice.[357] Decreased tumor growth after treatment with the rapamycin derivative everolimus suggested the importance of mTOR activation in this model. However, clinical trials failed to demonstrate significant treatment responses to mTOR inhibition by temsirolimus or ridaforolimus in LMS.[113,358,359]

Leiomyosarcoma Associated with Epstein-Barr Virus

Immunosuppression associated with solid transplantation and HIV infection can result in EBV-associated LMS, particularly in children and young adults.[46] Multicentricity is common. The histopathologic, immunohistochemical, and ultrastructural features are similar to the sporadic ones (Fig. 60-16). In situ hybridization with EBV-encoded RNA shows nuclear positivity in nearly all tumor cells (see Fig. 60-16, *inset*). EBV can infect smooth muscle cells, resulting in expression of latent and replicative viral products and production of infectious virus.[360] Reducing immunosuppression can lead to long-term remission.[361-363]

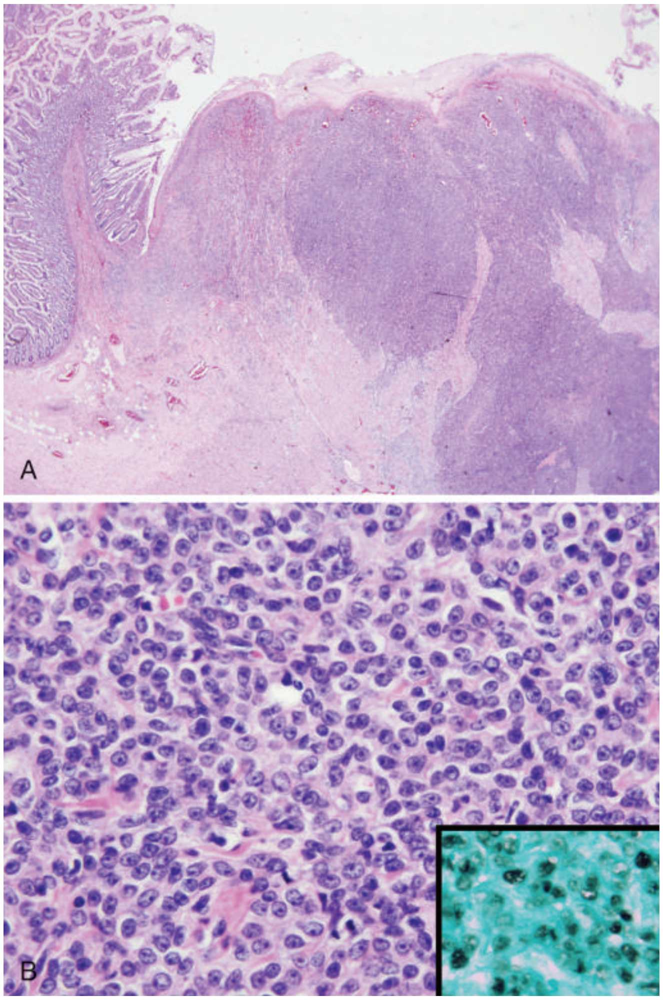

Figure 60-16 Epstein-Barr virus–associated smooth muscle tumor. **A,** Small intestine with large ulcerating and infiltrative submucosal mass. **B,** The tumor is cellular with spindled and round tumor cells with uniform nuclei and a distinct single nucleolus. VASCULAR TUMORS

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EHE) is a vascular tumor that most commonly develops in superficial or deep soft tissue of the extremities.[364] Other sites include the liver, bone, lung, skin, lymph nodes, and central nervous system.[365-370] EHE often seems to arise from a medium to large vein. Unlike epithelioid hemangioma, vascular differentiation in EHE is primitive with a solid growth pattern or in strands (Fig. 60-17). The stroma is usually myxoid. Tumor cells are large with abundant eosinophilic cytoplasm. Intracellular vacuoles are characteristic and represent early lumen formation sometimes containing erythrocytes. Occasionally there are associated eosinophils and lymphocytes. Focal cellular spindling, atypia, and necrosis are associated with a more aggressive course; however, a bland-appearing lesion may also metastasize.[371] The differential diagnosis includes metastatic carcinoma, melanoma, or various sarcomas with epithelioid appearance, in particular, epithelioid angiosarcoma and epithelioid sarcoma. Tumor cells are immunoreactive with vascular markers, such as CD31, factor VIII–related antigen, and CD34. Ultrastructurally, tumor cells reveal vascular differentiation with prominent cytoskeletal intermediate filaments, Weibel-Palade granules, pinocytosis, and basal lamina. Two translocation-associated gene fusions have been reported in EHE. t(1;3)(p36.3q25) in EHE results in the *WWTR1-CAMTA1* gene fusion.[372-374] CAMTA1 is a member of a family of calmodulin-binding transcriptional regulatory proteins, and WWTR1 (also known as TAZ) is a component of the Hippo pathway. Interestingly, this pathway has been implicated in infantile fibrosarcoma. In t(1;3)-negative tumors, RNA sequencing identified a *YAP1-TFE3* gene fusion.[375] *TFE3* translocation has also been described in alveolar soft part sarcoma (ASPS) and translocation-associated renal cell carcinoma, although with different fusion partners.

Extended periods of stable disease as well as partial spontaneous resolution have been noted.[376] Lower-grade lesions can be conservatively resected, whereas malignant lesions likely justify radical surgical resection. Although surgical resection can result in cure, about one third of patients will develop a local recurrence or distant metastasis, most commonly to the lung. Although EHE is considered to be chemoresistant, responses to carboplatin with etoposide and carboplatin with paclitaxel for aggressive pulmonary disease and to interferon-alfa 2 (IFN-2α) for multifocal or disseminated liver disease have been reported.[377-381] Targeting the VEGF pathway with sorafenib and bevacizumab has shown limited efficacy.[382-384] Thalidomide and lenalidomide have also demonstrated activity.[385,386]

Giant Cell Angioblastoma

Giant cell angioblastoma is a rare neonatal vascular tumor. Although the tumor grows slowly, it can be locally

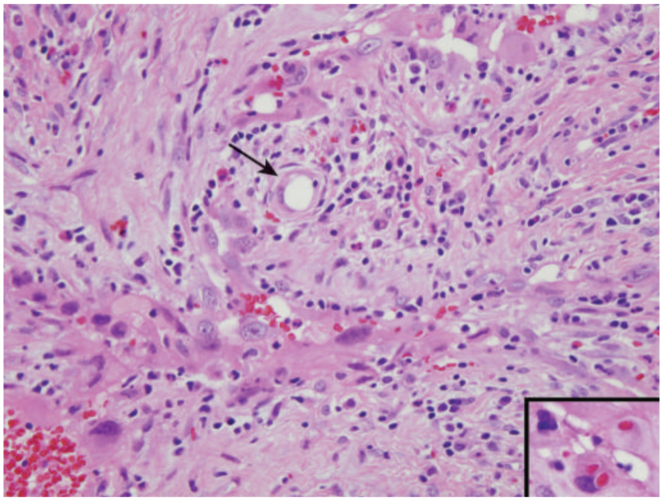

Figure 60-17 Epithelioid hemangioendothelioma. Poorly formed vascular channel lined by large epithelioid cells in an inflammatory stroma. Tumor cells have cytoplasmic vacuoles *(arrow)*. Red blood cells can be seen within cytoplasmic vacuoles *(inset)*.

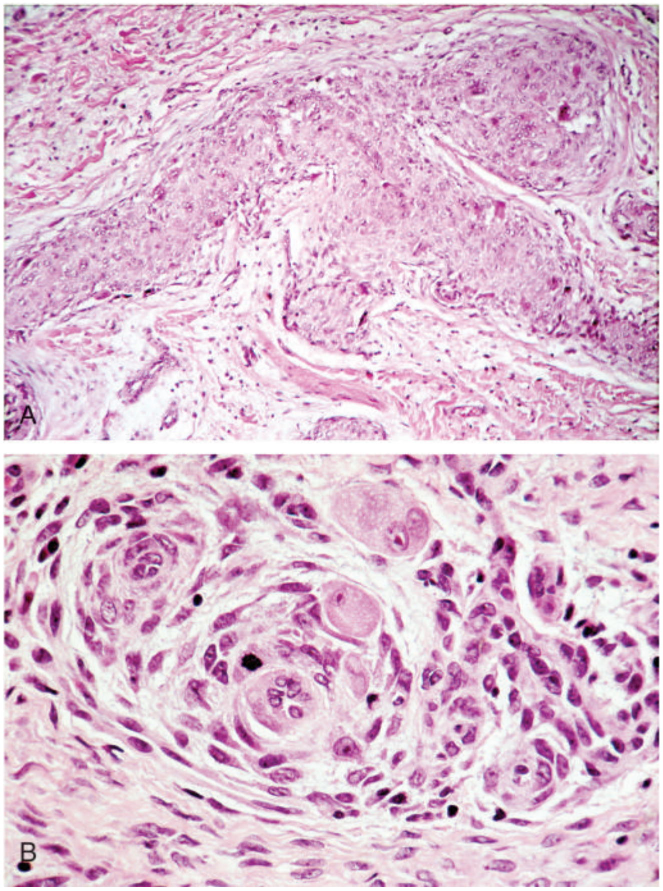

Figure 60-18 Giant cell angioblastoma. **A,** Nodular and plexiform aggregates of oval to spindle cells, mononuclear cells, and multinucleated giant cells in a perivascular distribution. **B,** Perivascular giant, spindled, and epithelioid cells.

invasive and highly destructive.[387,388] Histopathologically it consists of nodular and plexiform aggregates of oval to spindle cells, mononuclear cells, and multinucleated giant cells in a perivascular distribution. Like epithelioid sarcoma, this tumor mimics granulomatous inflammation (Fig. 60-18). Based on previous success with hemangiomas, two patients have been effectively treated with IFN-α2b.[389]

Kaposiform Hemangioendothelioma

Kaposiform hemangioendothelioma (KHE), a vascular tumor of infancy and childhood, occurs in either superficial or deep soft tissue. Large lesions, particularly in the retroperitoneum, are aggressive and present as consumption coagulopathy and thrombocytopenia (Kasabach-Merritt syndrome).[390] The lesions usually develop postnatally with a mean age at diagnosis of 3 years, 9 months. The lesions are multinodular, often with desmoplasia and vasoformative spindling of tumor cells resembling Kaposi sarcoma and glomeruloid structures (Fig. 60-19). Droplets of hyalin, fragmented erythrocytes, hemosiderin granules, and fibrin thrombi are characteristic. A lymphatic component is usually present. A majority of tumor cells are immunoreactive to CD31, CD34, and D2-40.[391] In contrast to infantile hemangiomas, GLUT1 is negative.[392] Tumors can spread locally but do not metastasize distantly.[393]

The mortality rate associated with KHE approaches 30%, typically resulting from Kasabach-Merritt phenomenon, which presents as consumption coagulopathy characterized by moderate microangiopathic hemolytic anemia, severe thrombocytopenia, and hypofibrinogenemia.[394] Although Kasabach-Merritt phenomenon is believed to be a consistent association with KHE, smaller lesions (<8 cm) may not result in sufficient platelet trapping to cause thrombocytopenia.[395] Large and invasive lesions are more likely to be associated with platelet trapping.[396] Surgical resection may be effective for superficial lesions. Unresectable tumors may respond to sirolimus, propranolol, ticlopidine, IFN-α, corticosteroids, vincristine, embolization, or low-dose radiation therapy.[397-402] For extensive disease, combination therapy with vincristine, cyclophosphamide, and dactinomycin with or without methotrexate may result in long-term remission.[403,404]

Spindled cells are immunoreactive with D2-40, a marker associated with lymphatic differentiation *(inset)*.

Kaposi Sarcoma

Kaposi sarcoma (KS) is an endothelial cell malignancy that results from transformation by human herpesvirus 8 (HHV-8, also known as Kaposi sarcoma herpesvirus).[405-407] KS can be multifocal and represent clonal or oligoclonal disease.[408,409] Four clinicoepidemiologic variants of KS are recognized: African (endemic), classic, acquired immunodeficiency syndrome (AIDS)-related (epidemic), and immunosuppression associated. Immunosuppression-associated KS can develop after solid-organ or bone marrow transplantation.[410] The incidence of AIDS-related KS has significantly decreased, likely owing to improvements in anti-HIV therapies.[411] KS in immunosuppressed individuals tends to behave aggressively, presenting as multifocal skin lesions and involvement of mucosal surfaces with spread to lymph nodes, brain, lung, gastrointestinal tract, and bones.[412-415]

The lymphadenopathic form of KS is most common in children; it is characterized by replacement of lymph nodes by a monotonous spindled cell proliferation, variable presence of slitlike vascular channels, and a lymphoplasmacytic infiltrate (Fig. 60-20, *A*). Spindled cells show striking nuclear reactivity for HHV-8 by in situ hybridization (see Fig. 60-20, *B*). HHV-8, like EBV, is a gammaherpesvirus, and, similar to immunosuppression-related EBV-associated lymphoproliferative disorder, KS may respond to reduced immunosuppression. KS also responds to pegylated liposomal doxorubicin and pegylated INF-2α.[416-419] Radiation therapy is effective for cutaneous disease.[420] Bevacizumab treatment was associated with an approximately 50% response rate in a phase II trial.[421] Preclinical evidence supports a role for mTOR inhibition acting through VEGF secretion and HSP90 inhibition acting through the viral latency-associated nuclear antigen (LANA).[422,423] Clinical responses to mTOR inhibitors have been observed.[424,425]

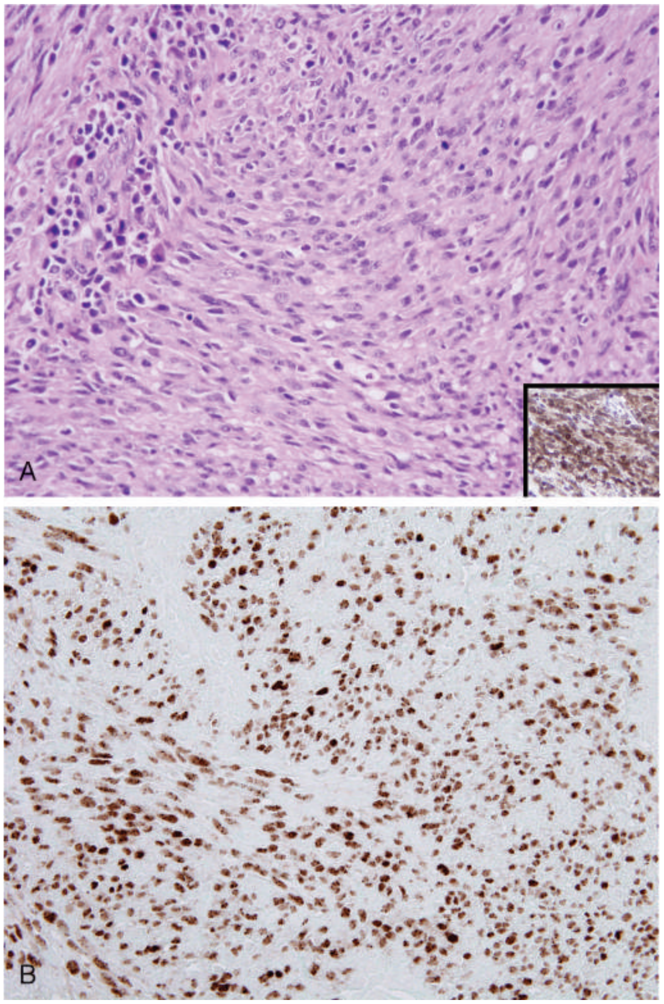

Figure 60-20 Kaposi sarcoma. **A,** Fascicles of monomorphic spindle cells and clusters of inflammatory cells, particularly lymphocytes and plasma cells. Spindled cells are strongly immunoreactive for D2-40 a lymphatic marker *(inset)*. **B,** The majority of tumor cells show nuclear staining for human herpesvirus 8 by in situ hybridization.

Angiosarcoma

Angiosarcomas are aggressive high-grade malignancies with endothelial differentiation that constitute approximately 2% of vascular tumors in children.[426] Angiosarcomas typically develop in skin or soft tissues.[427] In young children, angiosarcomas tend to occur in soft tissues and internal organs, including the liver, spleen, heart, and testes, and may be associated with Aicardi and Klippel-Trenaunay-Weber syndromes.[428-431] In adults, angiosarcoma development is associated with chronic lymphedema, prior radiation exposure, and exposure to vinyl chloride, arsenic, and thorium oxide.

Angiosarcomas are aggressive tumors with a 5-year survival of 20% to 40%.[432-435] Complete surgical resection is associated with survival.[436] Angiosarcomas have a high rate of local and distant recurrence and can metastasize to the regional lymph nodes, lungs, soft tissue, bones, liver, and brain.[427] Although tumors are typically resistant to chemotherapy and radiation, a partial response by unresectable tumors to chemotherapy may facilitate resection.[437] Docetaxel with radiation, paclitaxel, liposomal doxorubicin, vinorelbine, and metronomic trofosfamide may have efficacy in the treatment of these tumors.[438-442] Sorafenib or bevacizumab may be transiently effective for a subset of patients.[443,444] Radiation therapy is associated with decreased incidence of local recurrence.[433] Liver transplantation for hepatic angiosarcoma does not seem to result in increased survival, although long-term survival after transplantation has been reported for type II infantile hepatic hemangioendothelioma, which is considered a form of angiosarcoma.[445]

Angiosarcomas are vasoformative tumors with varying degrees of differentiation (Fig. 60-21). Tumor cells stain positive for factor VIII, CD31, CD34, and ERG, supporting an endothelial nature.[446,447] The cellular target of the antiangiogenic compound angiostatin, annexin II, is expressed in angiosarcoma.[448] Chromosomal gains at the *MYC* and *FLT4* loci can be detected in radiation-associated angiosarcoma.[449,450] Angiosarcomas are consistently positive for TEK (Tie2), and this kinase may serve as a therapeutic target.[451,452]

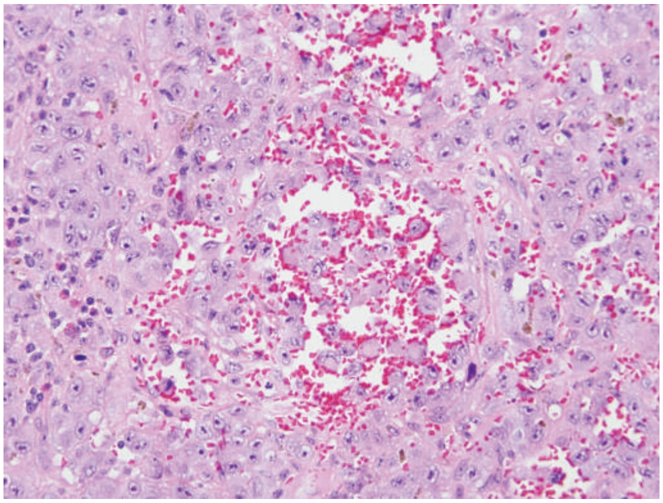

Figure 60-21 Angiosarcoma. High-grade angiosarcoma composed of large epithelioid cells with large pleomorphic nuclei, inclusion-like nucleoli, and abundant eosinophilic cytoplasm. There is vasoformation and hemorrhage.

CHONDROOSSEOUS TUMORS

Mesenchymal Chondrosarcoma

Mesenchymal chondrosarcoma is a rapidly growing, highly metastatic cartilaginous tumor. Although the majority develop in bone, more than 30% can develop in extraskeletal sites.[453] In contrast to most chondrosarcomas, mesenchymal chondrosarcoma tends to occur in young adults and, infrequently, children. Histopathologically, mesenchymal chondrosarcoma has two components: one consists of well-differentiated cartilage and the other of small cells resembling Ewing sarcoma (Fig. 60-22). Transition between these two components is usually abrupt. The small cell component frequently shows a hemangiopericytoma pattern of growth. The small cell component is immunoreactive with CD99, and the islands of cartilage are immunoreactive with S100 protein. Given its malignant behavior, patients with this tumor have a 38-month median survival with 5- and 10-year survival rates of 54.6% and 28%, respectively.[454,455] SOX9 expression can distinguish mesenchymal chondrosarcoma from small round blue cell malignancies.[456] Chromosomal translocation results in *HEY1-NCOA2* gene fusion in the majority of mesenchymal chondrosarcoma but not in other types of chondrosarcoma.[457] *HEY1* encodes hairy/enhancer of split, a component of the Notch signaling pathway. *NCOA2* encodes a transcriptional coactivator that functions with nuclear hormone receptors. *NCOA2* is a relatively promiscuous translocation partner contributing a carboxyl-terminal domain to gene fusion partners *ETV6 (TEL)* and *MYST3 (MOZ)* in a small number of leukemias, to *PAX3* in alveolar rhabdomyosarcoma, and to *AHRR* in soft tissue angiofibroma.[458-461] t(1;5)(q42;q32), resulting in *IRF2BP2-CDX1* fusion, has also been described.[462]

Extraskeletal Myxoid Chondrosarcoma

Rare in children and adolescents, extraskeletal myxoid chondrosarcoma (EMC), also known as chordoid sarcoma, typically develops in older adults, with a peak incidence in the fifth or sixth decade.[463-465] EMC is a slowly growing, occasionally painful, deep mass commonly in the extremities. Histopathologically, it exhibits a multinodular growth pattern with a prominent chondroid appearance. Tumor cells are uniform, are arranged in cords or strands, and are ovoid. The cytoplasm is usually eosinophilic and rarely has rhabdoid-type inclusions. Tumor cells are consistently immunoreactive to vimentin. About half weakly express S100 protein, and a lesser proportion are immunoreactive to cytokeratins, synaptophysin, and EMA.[466-469] SMARCB1 (INI1, SNF5) is deficient in about 10% of EMCs, and these tumors can be difficult to discriminate histologically for extrarenal rhabdoid tumor.[470] Like other STS, EMC has a significant propensity for late recurrences and pulmonary metastases.[471,472] Responses to sunitinib have been observed.[473]

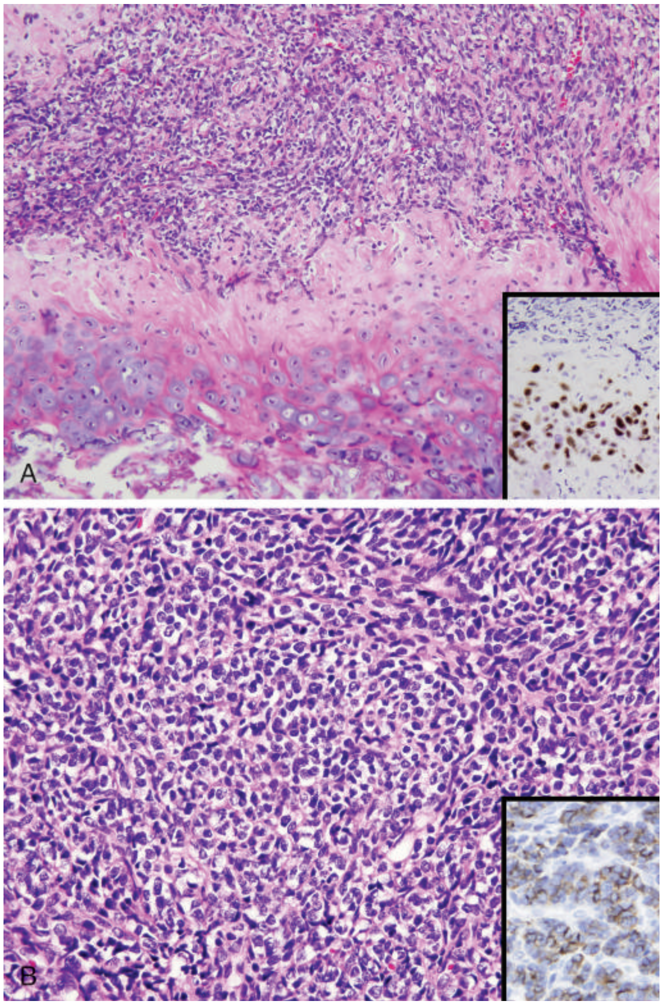

Figure 60-22 Mesenchymal chondrosarcoma. **A,** Biphasic tumor with a small cell Ewing sarcoma–like component at the top of the photograph and well-differentiated cartilage at the bottom. Cartilage component is strongly immunoreactive to S100 protein *(bottom of inset)*. **B,** The small cell component is shown at higher magnification demonstrating undifferentiated small cells with membranous CD99 immunoreactivity *(inset)*.

EMC is characterized by several recurrent clonal translocations. Approximately 75% harbor t(9;22)(q22;q12), which brings together the Ewing sarcoma gene *EWSR1* with *NR4A3 (CHN, TEC, NOR-1, MINOR)*.[474,475] Other translocations fuse *TAF15 (TAF2N, TAFII-68, RBP56)* and *TCF12* with *NR4A3*.[476-478] In contrast to EWSR1 and TAF15, which are ubiquitously expressed RNA binding proteins and translocated in many sarcomas, TCF12 is a basic helix-loop-helix transcription factor that contributes its DNA-binding domain to the *NR4A3* fusion.[479,480] NR4A3 is a member of a family of orphan nuclear receptors that includes NUR77 (NR4A1) and NURR1 (NR4A2).[481-484] In contrast to typical nuclear receptors such as the estrogen receptor that require binding to a ligand for activity, the NR4A family of transcription factors regulate transcription in a ligand independent fashion.[485] Their activity is controlled by regulated expression and posttranslational modification by phosphorylation.[486-490] The NR4A family has been implicated in a variety of cellular processes, including T- and B-cell apoptosis and hepatic glucose metabolism.[491-493] Mice deficient for both *Nr4a1* and *Nr4a3* develop acute myeloid leukemia in the early postnatal period.[494] The fusion of *EWSR1* with *NR4A3* results in an increase in transactivation activity over the native *NR4A3*.[495] Targets of the oncogenic fusion are not known; however, expression profiling of EMC with differing histologies and translocations demonstrated a consistent RNA profile distinct from that of myxoid liposarcoma (which is characterized by an *EWSR1-DDIT3* fusion).[496] *PPARG* and *NDRG2* have been identified as transcriptional targets for EWS-NR4A3.[497]

TUMORS OF UNCERTAIN DIFFERENTIATION

Synovial Sarcoma

Synovial sarcoma typically originates in proximity to major articular structures, bursae, and tendon sheaths, particularly of the proximal lower extremity. In spite of its name, a true relationship with synovium is no longer believed and intraarticular location is exceptional. Other sites for synovial sarcoma development include the trunk, head and neck, and mediastinum.[498-500] Synovial sarcoma is classified into two histologic subtypes, the more common monophasic spindle cell morphology subtype and a biphasic subtype (Fig. 60-23). Both subtypes exhibit an undifferentiated spindled cell component. In addition, the biphasic subtype has a variable degree of epithelial differentiation in the form of glandular structures or clusters of poorly organized epithelial cells. A small proportion of cases are characterized by small round cells with an organoid, hemangiopericytomatous pattern mimicking Ewing sarcoma (see Fig. 60-23, C). This group is associated with a worse prognosis. Glandular structures, epithelial clusters, and focally the spindle cell component show intense immunoreactivity for keratin and EMA.

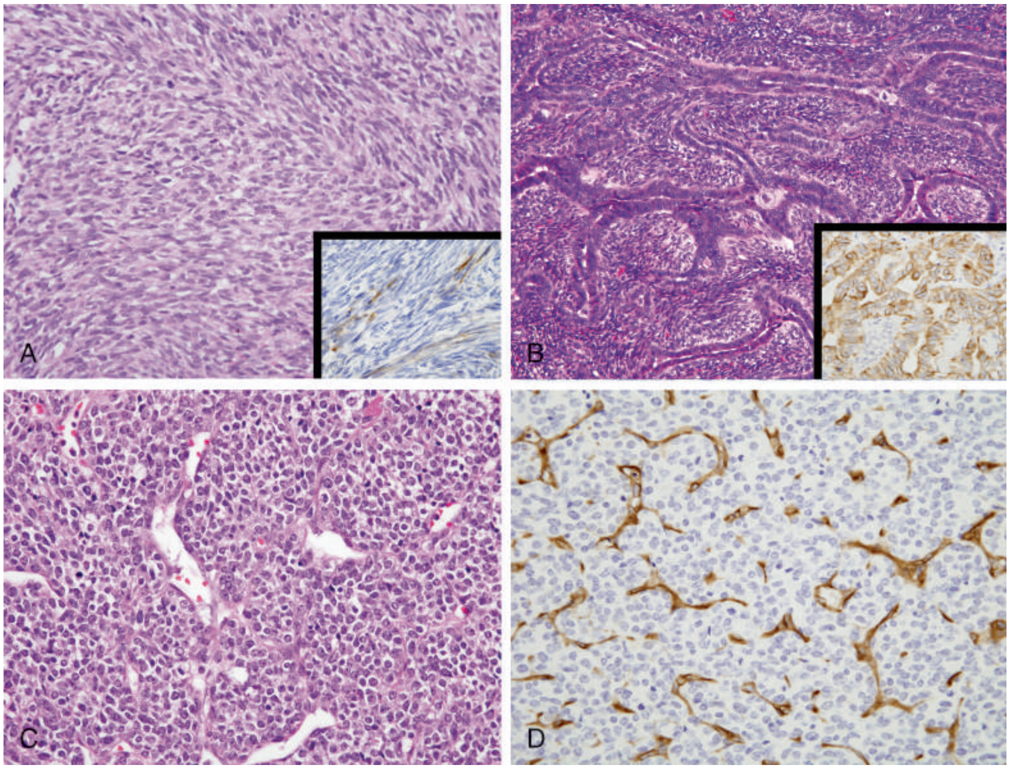

Figure 60-23 Synovial sarcoma. **A,** Monophasic synovial sarcoma composed of cellular undifferentiated spindled cells. Focal immunoreactivity for epithelial membrane antigen *(inset)*. **B,** Biphasic synovial sarcoma with prominent slitlike glandular component and intervening undifferentiated spindled cells. The glandular component is strongly immunoreactive to cytokeratins *(inset)*. **C,** Small round cell synovial sarcoma with a hemangiopericytoma-like pattern mimicking a malignant primitive neuroectodermal tumor. **D,** Malignant primitive neuroectodermal tumorlike synovial sarcoma showing characteristic vessels highlighted by CD34-immunoreactive endothelium.

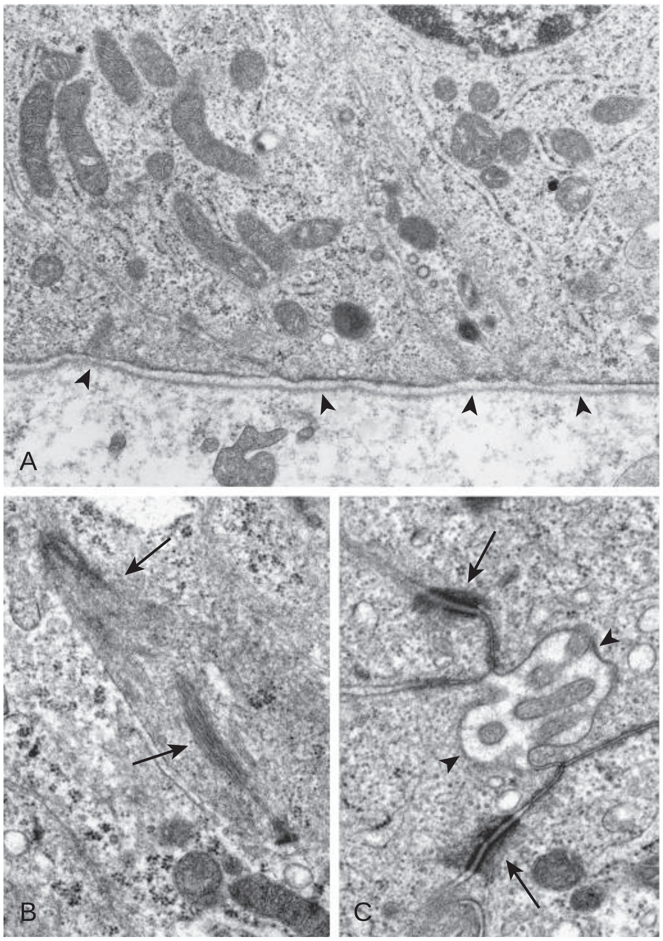

Figure 60-24 Synovial sarcoma. **A,** Groups of tumor cells are invested by a well-formed, continuous basal lamina *(arrowheads)*. **B,** Well-developed cytoplasmic tonofilaments *(arrows)*. **C,** Rudimentary intercellular lumen with microvilli *(arrowheads)* and well-developed desmosomes *(arrows)*.

Ultrastructurally there is evidence of epithelial differentiation with basal lamina, cell junctions, and microvilli in both glandular and spindle cell components (Fig. 60-24).

Cytogenetically, more than 95% of synovial sarcomas are characterized by t(X;18)(p11;q11), which results in the fusion of *SS18* (also known as *SYT*) with *SSX1, SSX2,* or *SSX4*.[501-506] A variant fusion of the SS18-related gene *SS18L1* at 20.q13.3 with *SSX1* has also been reported.[507] Identification of the fusion by RT-PCR assay in paraffin-embedded tissue is an important diagnostic tool with a sensitivity of 95% and a specificity of 100%.[508-512] Nuclear immunostaining of SS18 in paraffin-embedded tissue has a sensitivity of 85%.[513]

SSX1, SSX2, and *SSX4* are distinct genes that are located in proximity on the X chromosome.[514] SSX1 and SSX2 are highly conserved proteins characterized by acidic carboxyl and amino termini with homology to the Kruppel-associated box (KRAB), which, in the context of a DNA-binding protein, has been implicated in transcriptional repression.[515] The translocations found in synovial sarcoma encode nearly full-length *SS18* fused to the carboxyl terminus of SSX.[506] SS18 and the SS18-SSX chimeras demonstrate nuclear localization in a speckled distribution.[516,517] SS18 is an integral component of the SWI/SNF (BAF) chromatin remodeling complex.[518-521] SS18-SSX competes with normal SS18, resulting in an aberrant BAF complex lacking SMARCB1 (SNF5). The aberrant *BAF* complex activates *SOX2,* and *SS18* overexpression displaces *SS10-SSX* binding, decreasing *SOX2* expression and cell proliferation.[521] SS18-SSX–associated SWI/SNF disruption places synovial sarcoma in a class of tumors that share aberrancy of this large multiprotein complex, including malignant rhabdoid tumors (see later) and a growing number of epithelial cancers. Moreover, an increasing number of proteins have been found to be components of the mammalian SWI/SNF complex, increasing the number of tumors in which mutations in the genes that encode for these proteins have been identified.[522] Gene expression studies in human pluripotent stem cells expressing SS18-SSX indicated that expression changes virtually always represented gene activation.[523] Intriguingly, only half of the genes are regulated by SS18-SSX in mesenchymal stem cells, supporting an emerging theme in chromatin biology that cell lineage–specific epigenetic differences are critical in determining the gene expression consequences. Human synovial sarcoma likely derives from an early stem cell because tumors and cell lines consistently express stem cell marker genes *OCT3/4, NANOG,* and *SOX2*.[524] SS18 was also found to interact with a nuclear coactivator (SIP/CoAA) that shares regional homology with EWS and TLS/FUS.[525,526] The SS18-SSX1 fusion demonstrates transforming activity in a rat fibroblast cell line not shared by SS18 or SSX1 alone.[527] Tissue-specific activation of *SS18-SSX2* fusion controlled by the ubiquitous ROSA26 promoter in a conditional knock-in system by myoblast Myf5-activated Cre results in tumor development in 100% of surviving mice between 3 and 5 months of age (100% penetrance).[528] The mouse tumor shares histopathology with human synovial sarcoma, exhibiting both monophasic and biphasic components, and it has been shown that some mouse tumors shared gene expression profiles. Intriguingly, the timing of SS18-SSX2 expression plays a critical role in the resulting phenotype. Expression of SS18-SSX2 in early embryos was lethal, whereas expression in developing myocytes resulted in myopathy.

Several studies have attempted to identify pathologic and clinical differences between tumors harboring the most common fusions. Pathologically, tumors harboring the *SSX1* fusions demonstrate biphasic morphology and increased Ki67 staining, whereas those with the *SSX2* fusions are monophasic.[529,530] Although a large multicenter study comparing the outcome of patients with tumors harboring the *SS18-SSX1* fusion to those with the *SS18-SSX2* fusion demonstrated that the *SSX1* fusion predicted a worse outcome,[531,532] a more recent multicenter study failed to confirm this finding but demonstrated that histologic grade was a strong predictor of survival.[533,534] An analysis of cell cycle–related proteins demonstrated that tumors with the *SS18-SSX1* fusion express higher levels of cyclin A and D1 relative to those with *SSX2* fusion.[535,536] Although there are biologic and epidemiologic differences between these fusions, these differences are likely to be subtle.

In addition to the *SSX* fusions, other genes have been associated with synovial sarcoma biology. The expression of IGFR1 has been shown to correlate with a high incidence of lung metastases.[537] A significant fraction of synovial sarcoma also express hepatocyte growth factor (HGF) and/or its receptor MET.[538] Expression of HGF or coexpression of MET and HGF were associated with large, high-grade and high-stage tumors and correlated with decreased survival.[539] Synovial sarcoma–specific gene expression patterns have been identified. Compared with undifferentiated pleomorphic sarcoma, synovial sarcoma shows increased expression of several growth factors and receptors, notably insulin-like growth factor–binding protein 2 (IGFBP2), the receptor tyrosine kinase HER2 (ERBB2), IGF-2, and fibroblast growth factor receptor 3 (FGFR3).[540] Activation status of AKT/mTOR correlates with decreased EFS.[541] Compared with other STS, synovial sarcoma demonstrated increased expression of genes involved in the Wnt or notch signaling pathway, including *TLE1,* which was shown to immunohistochemically discriminate synovial sarcoma from other sarcomas.[542,543] SS18-SSX mediates Wnt signaling by interacting with β-catenin in the nucleus, and small molecule inhibition of Wnt signaling in transgenic mice resulted in decreased tumor growth.[544,545]

Recent studies have begun to explore the role of immune-directed therapy for synovial sarcoma based on the consistent expression of the tumor antigen NY-ESO-1.[546,547] However, a pilot study of the anti-CTLA4 antibody ipilimumab was discontinued owing to disease progression.[548]

Alveolar Soft Part Sarcoma

ASPS is a malignant tumor that usually presents in the thigh and trunk of young adults but can develop in the orbit or tongue in children.[549-551] Unusual primary locations include breast, heart, bladder, vagina, and uterine cervix.[552-556] About 25% of patients present with metastatic disease.[557] Because ASPS can metastasize to the brain in addition to lung and bone, the staging evaluation should include head CT. Complete surgical resection is associated with long-term survival.[558,559] ASPS is generally considered to be resistant to chemotherapy, although a small fraction of patients may respond.[557] Although pulmonary metastases may demonstrate response to treatment with vincristine, cyclophosphamide, and doxorubicin alternating with etoposide and ifosfamide, chemotherapy does not seem to extend survival.[560] Although considered an indolent tumor, ASPS carries a poor prognosis, given the insidious propensity for late metastases. Despite localized disease at presentation, subsequent distant recurrence results in a 77% survival at 2 years, 60% at 5 year, 38% at 10 years, and 15% at 20 years in adults.[561,562] Long-term survival in the pediatric population is significantly better with 5- and 10-year OS of 87% and 78%, respectively.[557] Given the protracted course of ASPS, metastatic disease can be palliated by resection of metastatic disease to lung and brain.[563-565] ASPS seems particularly responsive to VEGF-directed therapy, an observation consistent with gene expression profiling demonstrating elevated expression of several genes associated with angiogenesis.[566] Becvacizumab, sunitinib, and cediranib have efficacy in advanced ASPS.[567-571] Trabectedin may also be effective.[572,573]

Histologically, ASPS is characterized by an organoid, pseudoalveolar proliferation of large polygonal cells that range from eosinophilic to clear (Fig. 60-25). Intravascular tumor growth is often present. A characteristic of these tumors is the presence of cytoplasmic periodic acid–Schiff-positive crystalline structures visible on light and electron microscopy. Ultrastructurally these membrane-bound crystals consist of a latticework with distinctive periodicity (Fig. 60-26). The crystals are composed of monocarboxylate transporter protein MCT1 and its chaperone CD147.[574] The cell of origin for ASPS remains unclear, with refuted evidence suggesting a myogenic or neural crest derivation.[575,576] Tumor cells may show focal

positivity for actin or desmin, but these markers are not muscle specific.

ASPS is characterized by a unique chromosomal translocation, t(X;17)(p11;q25).[577,578] The translocation is frequently unbalanced, consistently resulting in the fusion of *TFE3* with *ASPSCR1* (also known as *ASPL*).[579] *TFE3* is a member of the MiT basic helix-loop-helix leucine zipper transcription factor family.[580,581] ASPSCR1 is not well characterized. However, amino acid sequence similarity suggests that ASPSCR1 may be the human homolog of mouse Tug, a protein that regulates intracellular trafficking of the glucose transporter GLUT4.[582] The *ASPSCR1-TFE3* translocation may dysregulate *TFE3* expression by placing it under the control of the ubiquitous *ASPSCR1* promoter. Alterations in the *TFE3* locus can be detected cytogenetically, by FISH or PCR assay. In addition, nuclear immunoreactivity for TFE3 provides a sensitive and possibly specific marker.[583] ASPSCR1-TFE3 likely functions by altering target gene transcription. *ASPCR1-TFE3* translocation can also be found in pediatric translocation-associated renal carcinoma, and *TFE3* can also be translocated in perivascular epithelioid cell neoplasm and epithelioid hemangioendothelioma.[375,584,585] One potential target gene with therapeutic potential is the receptor tyrosine kinase MET, although a clinical trial of tivantinib demonstrated modest effect.[586,587] TFE3 fusions may also regulate the mTOR pathway, suggesting activity of inhibitors of this pathway.[588] The biologic importance of aberrant *TFE3* in ASPS classifies it together with a growing number of other MiT family–associated tumors, including clear cell sarcoma (see later), translocation-associated renal carcinoma, and melanoma.

Clear Cell Sarcoma

Clear cell sarcoma (CCS) is a slowly growing soft tissue tumor that typically arises in the tendons, aponeuroses, and fascial structures of the extremities of adolescents and young adults.[589,590] It often presents as a small (<5 cm) painful nodule around the ankle or foot. CCS has a propensity for late metastasis, regionally to lymph nodes and distantly to lungs and bone. Overall, CCS is associated with a 5-year survival of 40% to 70%, with children faring somewhat better than adults.[591-594] Aggressive surgical management is critical to achieve disease control. In a pediatric population, fully resected and small tumors (<3 cm) are associated with a 5-year EFS of 90% to 100% whereas larger tumors (>10 cm) result in a 20% 5-year EFS.[593] Postoperative radiation therapy is probably not necessary for fully resected CCS but may result in improved local control when negative margins cannot be achieved, a situation that frequently arises because complete surgical excision with wide margins at common locations is often not feasible without amputation. Unresectable, metastatic, relapsed CCS is refractory to conventional chemotherapy; however, postoperative chemotherapy may be of benefit for localized resectable disease.[85,595] Responses to sorafenib and sunitinib have been observed.[596,597] Although MET activation by HGF was demonstrated in clear cell sarcoma, clinical trials of tivantinib have had limited efficacy.[587,598]

Clear cell sarcoma has an infiltrative, nesting and fascicular pattern of growth (Fig. 60-27). The nesting pattern is highlighted by a reticulin framework. Tumor cells are usually ovoid or spindle with ovoid to elongated nuclei and distinct prominent eosinophilic nucleoli. CCS shares several histologic, immunophenotypic, and ultrastructural similarities with cutaneous melanoma, leading to the frequent designation of this tumor as “malignant melanoma of the soft parts.”[590] Melanocytic differentiation of CCS is demonstrated by the expression of melanoma markers, including MITF, HMB45, S100, neuron-specific enolase (NSE), and melastatin.[599,600] Furthermore, about 70% of CCSs reveal melanin pigment by hematoxylin and eosin or Fontana stains and, ultrastructurally, they may contain premelanosomes and melanosomes.[600-602] By microarray expression analysis, CCS segregates from other sarcomas based on a

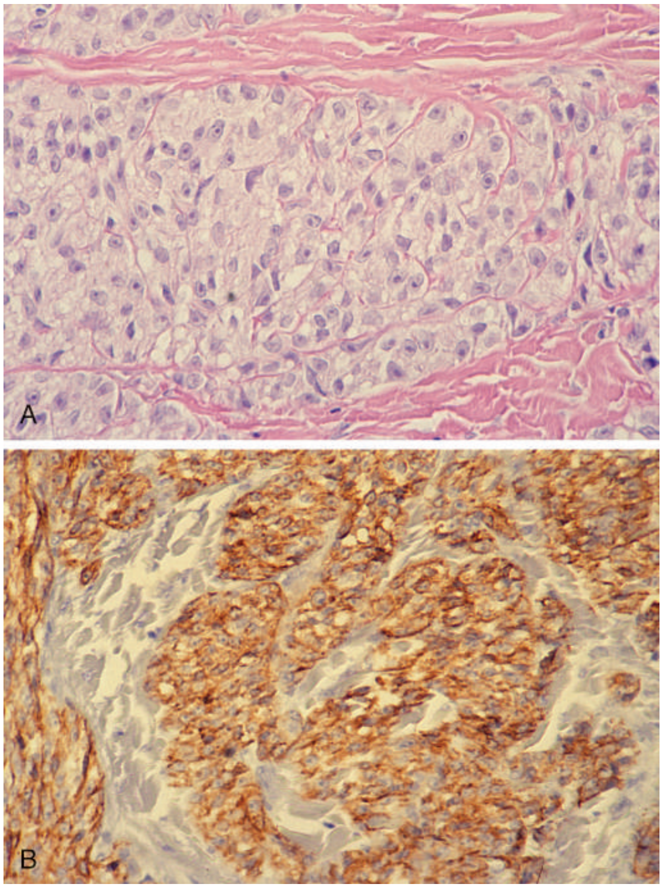

Figure 60-27 Clear cell sarcoma. **A,** Well-defined nest of tumor cells surrounded by fibrous septa. Tumor cells have abundant pale-staining cytoplasms and rounded vesicular nuclei with prominent single centrally located nucleolus. B, Tumor cells are strongly immunoreactive for HMB45, a melanoma marker. Strong staining for S100 protein is also characteristic of clear cell sarcoma *(not shown)*.

melanocytic expression pattern.[603,604] However, clinically and cytogenetically, CCS and cutaneous melanoma are distinct. CCS presents as isolated masses in deep soft tissue, often originating from tendons and aponeuroses. CCS rarely shows the degree of anaplasia or microsatellite instability associated with melanoma and, unlike with melanoma, *BRAF* is not mutated.[605-607] The vast majority of CCS tumors are distinguished by t(12;22)(q13;q12) that results in fusion of the Ewing sarcoma gene *EWSR1* with the CREB transcription factor family member *ATF1*.[608] The *EWSR1-CREB1* gene fusion is less commonly observed in soft tissue CCS but is more common in gastrointestinal CCS. These translocations are not found in cutaneous melanoma. Native ATF1 is regulated by serine phosphorylation in response to cyclic AMP levels by protein kinase A.[609,610] In CCS, translocation dysregulates ATF1 activity by replacing the kinase-inducible domain of *ATF1* with the amino-terminal region of *EWSR1*.[611] *Ewsr1-Atf1* expression in mice resulted in the high penetrance development of tumors that shared histologic and immunohistochemical features with the human tumor.[612,613]

Induction of MITF expression by EWSR1-ATF1 links the melanocytic phenotype of CCS with tumor proliferation/survival.[607] MITF, a member of the MiT basic helix-loop-helix leucine zipper transcription factor family, is the master regulatory factor of melanocyte differentiation and survival.[581,614] EWS-ATF1 coopts the typically melanocyte-stimulating hormone (MSH)-regulated cyclic AMP response element in the *MITF* promoter, aberrantly activating *MITF*. A critical transcriptional target, MITF mediates both the survival and proliferation of the melanocytic phenotype of CCS. TFE3 and TFEB, other members of the MiT transcription factor family, can rescue the effect of inhibited MITF expression in CCS.[607] This functional redundancy places CCS among a family of tumors that share aberrant MiT transcription factor family expression, including cutaneous melanoma, ASPS, and translocation-associated renal cell carcinoma. A gastrointestinal form of CCS is associated with a translocation that brings together *EWSR1* with *CREB1*.[615] Despite the related activity of *CREB1* with *ATF1*, this form of clear cell sarcoma does not express MITF or markers of melanocytic differentiation. Microarray expression profiling of the gastrointestinal CCS demonstrates a pattern that clusters more closely with angiomatoid fibrous histiocytoma (AFH) than soft tissue CCS (see later).[616]

Epidermal growth factor signaling may be important for CCS development. Clear cell sarcoma cell lines express ERBB3 and either ERBB2 or ERBB4.[603,617] Furthermore, ERBB3 is constitutively phosphorylated in cells, expressing its ligand neuregulin (NRG1), and can be activated by exogenous neuregulin in those cells that are not activated in an autocrine fashion. Treatment with the pan-ERBB inhibitor CI-1033 decreases cell proliferation.[617]

Desmoplastic Small Round Cell Tumor

Desmoplastic small round cell tumor (DSRT) typically arises in intraabdominal soft tissues. It has a strong predilection for males. Although its most common site is the peritoneum, DSRT can arise in kidney, testes, ovaries, pleura, scalp, ethmoid sinuses, and pancreas.[618-622] DSRT usually presents as abdominal pain and weight loss and is frequently locally or distantly metastatic at the time of diagnosis. The diffuse paraserosal spread of DSRT may prevent resection with negative margins. A high tumor response rate in untreated DSRT and previously treated DSRT to high-dose cyclophosphamide, doxorubicin, and vincristine (HD-CAV) alternating with ifosfamide and etoposide may cytoreduce bulky disease, permitting surgical resection and radiation therapy, if necessary.[623] Although the results are mixed, patients with high-risk disease may benefit from consolidation with high-dose chemotherapy and autologous stem cell rescue.[624,625] Relapsed disease may respond to irinotecan and temozolomide or low-dose cyclophosphamide and vinorelbine.[626,627] Because DSRT tends to develop and spread widely in the peritoneum, based on its efficacy for peritoneal carcinomatosis, the use of continuous hyperthermic peritoneal infusion of chemotherapy is being studied, although initial results do not appear promising.[626,628] Multimodality therapy was associated with a 3-year

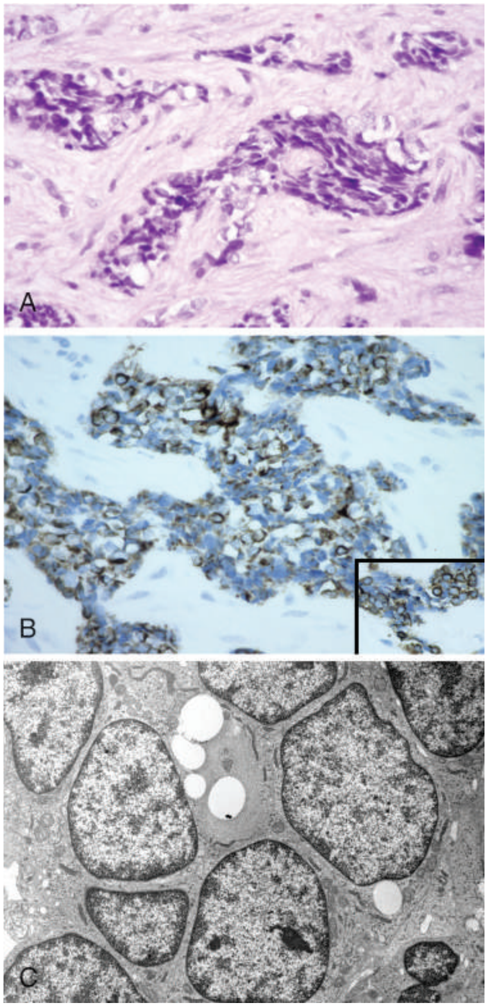

Figure 60-28 Malignant desmoplastic small round cell tumor. **A,** Infiltrative growth of elongated nests of variable size immersed in a densely collagenous stroma. Tumor cells are small and round or ovoid with hyperchromatic nuclei and poorly defined cytoplasmic borders. **B,** Tumor cells show strong diffuse and dotlike cytoplasmic immunoreactivity for desmin and diffuse cytoplasmic immunoreactivity for cytokeratin *(inset)*. **C,** Ultrastructurally, a cluster of undifferentiated small tumor cells with uniform round nuclei and occasional cytoplasmic whorls of intermediate filaments is evident.

survival of 55% compared with 27% when all three modalities were not used. Gross tumor resection was associated with a 58% 3-year survival compared with no survivors in the nonresection control.[629] However, despite multimodality therapy, long-term survival remains very low.

As the name implies, DSRT appears histologically as malignant undifferentiated small round cells typically associated with a prominent desmoplastic reaction (Fig. 60-28).[630] Desmoplastic stroma, however, is not always present, and location of the tumor may play a role in this regard. For example, DSRT originating in the kidney characteristically lacks desmoplastic stroma.[618] Some tumors have glandular or rosettelike epithelial differentiation. Nuclei are usually hyperchromatic with little pleomorphism, dispersed chromatin, and small nucleolus. The scant cytoplasm is poorly outlined. A rhabdoid-type cytoplasmic inclusion can be observed focally in about half of the cases. Areas of necrosis and frequent mitoses are common. Multiphenotypic differentiation is characteristic immunohistochemically. Most cases show immunoreactivity for cytokeratin, EMA, vimentin, and desmin. Desmin and vimentin often show a dotlike intracytoplasmic pattern corresponding to the rhabdoid-type inclusion. Nuclear WT1 expression with antibodies to the carboxyl terminus is usually observed. Ultrastructurally, tumor cells are primitive, are organelle poor, and may show paranuclear whorls of intermediate filaments (see Fig. 60-28, C). Cell junctions including desmosomes may be observed focally.

Molecularly, DSRT is characterized by t(11;22)(p13;q12), which fuses the Ewing sarcoma gene *EWSR1* with *WT1*.[631-634] Although there is variability in the structure of the resulting chimera, the most common fusion includes *EWSR1* exons 1 to 7 and *WT1* exons 8 to 10.[634,635] WT1 is a Cys$_2$-His$_2$ zinc finger DNA-binding protein that shares a high degree of homology and DNA recognition motif with the growth factor–stimulated zinc finger DNA-binding protein EGR1.[636-639] The most common translocations result in *EWSR1-WT1* chimeras that preserve three of the four zinc finger motifs; however, owing to molecular heterogeneity, chimeras may lack *EWSR1* or *WT1* exons.[635] The *EWSR1-WT1* fusion has been detected in two intraabdominal tumors with histologic features of epithelioid leiomyosarcoma but lacking desmoplastic stroma, suggesting either a variant DSRT or another tumor type marked by *EWSR1-WT1*.[640] Based on the paradigm of the other transcription factors fused to the Ewing sarcoma gene, *EWSR1-WT1* is believed to exert its oncogenic activity through transcriptional mechanisms, and several putative transcriptional targets have been identified. The EWSR1-WT1 fusion activates platelet-derived growth factor alpha (PDGFA), T-cell acute lymphoblastic leukemia–associated antigen 1 (TALLA-1), and interleukin-2/15 receptor expression.[641-643] DSRTs stain positive for PDGF and IGF-2.[644] As a mitogen potentially acting on tumor-associated fibroblasts, PDGF seems a plausible cause for the desmoplastic reaction characteristic of these tumors. However, immunohistochemical analysis demonstrated an inverse correlation of PDGF expression with desmoplasia.[645] Although PDGF expression might suggest therapeutic PDGFR inhibition, imatinib demonstrated little to no activity as a single agent for DSRT.[646] About one third of DSRTs stain positive for androgen receptor, and androgen blockade may result in some response.[647]

Angiomatoid Fibrous Histiocytoma

Angiomatoid fibrous histiocytoma (AFH) was first described by Enzinger.[648] Histopathologically, it consists of a nodular fibrohistiocytic proliferation that is usually surrounded by lymphoid follicles and a lymphoplasmacytic infiltrate (Fig. 60-29). The lesion often undergoes focal cystification and hemorrhage. In contrast to the more common (and similar sounding) adult tumor malignant fibrous histiocytoma (currently classified as high-grade undifferentiated pleomorphic sarcoma [see later]), the current WHO classification of STS no longer

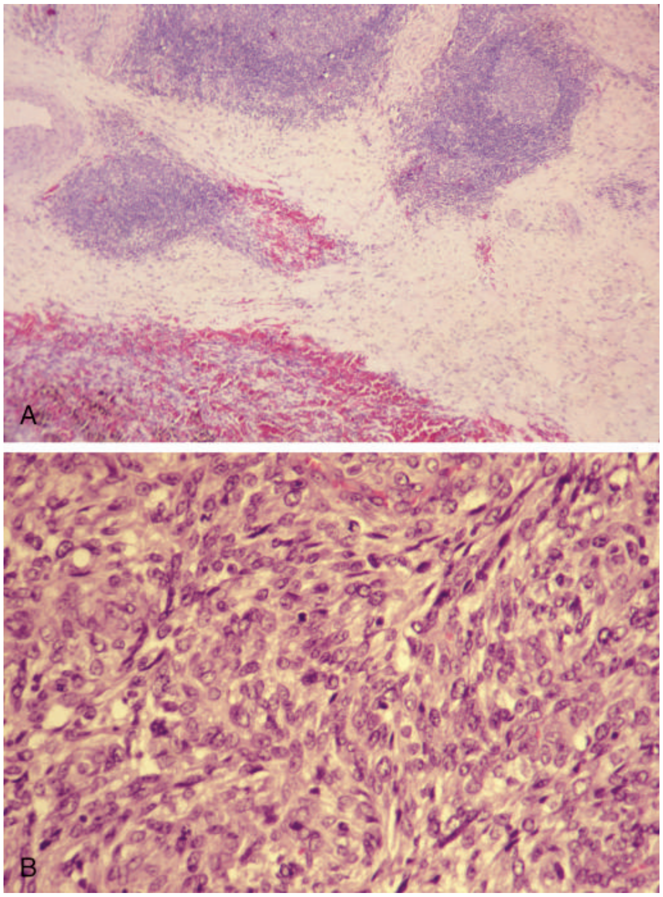

Figure 60-29 Angiomatoid fibrous histiocytoma. **A,** Nodular spindle cell proliferation with hemorrhage *(bottom)* and peripheral fibrous tissue with well-formed lymphoid follicles. **B,** Histiocyte-like cells and fibroblasts poorly arranged in short fascicles.

considers AFH a malignancy. Surgery is considered curative treatment. However, incomplete resection is associated with a significant rate of local recurrence. Metastases to lung and brain have been reported in a single case in an adult with a large tumor.[649]

AFH is associated with a translocation of *EWSR1* or its related protein FUS1 with *CREB1* or the related CREB family member *ATF1*.[616,650,651] These translocations are also characteristic of clear cell sarcoma (see earlier) and have been reported in primary pulmonary myxoid sarcoma.[652] In contrast to typical CCS, these tumors do not express markers of melanocytic differentiation, including MITF. Because *SOX10* is required for *CREB1/ATF1*-mediated *MITF* activation, the differences in expression may reflect the absence of *SOX10* in AFH.[607]

Extrarenal Rhabdoid Tumor

Soft tissue rhabdoid tumor is a high-grade malignant tumor that occurs almost exclusively in infants and children. A subset is congenital, and some of these may be disseminated at presentation.[653-655] Similar to its counterpart of renal origin, extrarenal rhabdoid tumor is an aggressive tumor with a very high rate of distant metastases, most commonly to the lung, lymph nodes, and liver.[656] Soft tissue rhabdoid tumors usually occur in the deep soft tissue, particularly in the paraspinal and neck regions. Some tumors arise adjacent to cutaneous benign mesenchymal lesions.[657,658] Tumor cells have little cohesiveness and grow in sheets or in a pseudoalveolar pattern, often mimicking alveolar rhabdomyosarcoma. Tumor cells are of medium size and are rounded with large eccentric nuclei and a prominent eosinophilic nucleolus. Typically, the cytoplasm contains a paranuclear eosinophilic inclusion. Although extrarenal and renal rhabdoid tumors in children form a discrete entity, soft tissue rhabdoid tumors in adolescents and adults are a heterogeneous group without consistent cytogenetic aberrations.

A majority of tumor cells are immunoreactive for vimentin, EMA, and cam5.2. CD99, synaptophysin, and NSE are also frequently positive. Actin, S100 protein, desmin, myogenin, and CD34 are negative. Ultrastructurally, the rhabdoid inclusion corresponds to a paranuclear whorl of intermediate filaments.

Cytogenetic analysis of rhabdoid tumor consistently demonstrates abnormalities of 22q11.[659] These changes include deletions and translocations. Mapping the deleted region in rhabdoid tumor cell line implicated the *SMARCB1 (hSNF5, INI1, BAF47)* gene, which was found to be mutated and truncated in other tumors.[660,661] SMARCB1 is a component of the multiprotein SWI/SNF adenosine triphosphate (ATP)-dependent chromatin remodeling complex. Mutations that disrupt SWI/SNF function have been identified in a growing number of human cancers in children and adults.[522] Loss of SMARCB1 results in polyploidization and chromosomal instability of rhabdoid cells. Expression of wild-type SMARCB1 results in cell cycle arrest, possibly through restoration of DNA damage-responsive cell cycle checkpoints or replicative senescence, processes mediated by CDKN2A and CDKN1A.[662,663] For further discussion of rhabdoid tumor of the kidney and central nervous system atypical teratoid/rhabdoid tumor, see Chapters 55 and 57.

Epithelioid Sarcoma

Epithelioid sarcoma is a distinctive high-grade soft tissue neoplasm that arises most commonly in the distal extremities of adolescents and young adults, particularly in the fingers, wrists, and hands. In young children, the tumor is more likely to arise in the head and neck as well as the pelvis.[664-667] The tumor can present as a superficial ulcerated lesion or a deep, often painful, mass. Dermis, subcutaneous tissue, fascia, and tendons can be involved, and on recurrence the tumor has a propensity for local spread along fascial planes and neurovascular bundles, resulting in the formation of proximal tumor satellites. Histologically, these tumors may resemble MPNSTs, synovial sarcoma, CCS, rhabdoid tumor, and melanoma.[668] The occurrence of intravenous extension or lymph node involvement is predictive of a very high rate of pulmonary metastases.[669,670] In adults, epithelioid sarcoma demonstrates a 77% risk for local recurrence and a 45% risk for metastatic disease.[671] Survival in children with epithelioid sarcoma exceeds that in adults.[672] In children, epithelioid sarcoma is associated with a 5-year EFS of 61% and an OS that declines from 92.4% at 5 years to 86.9%

and 72% at 10, and 15 years, respectively, indicating the propensity for late recurrence.[673] A small series of children with epithelioid sarcoma demonstrated that after lymphadenectomy with or without irradiation, all patients were free of disease approximately 10 years after diagnosis.[6] Tumor size is the best predictor of prognosis, with tumors larger than 5 cm associated with a worse prognosis.[673,674] Wide local excision with negative margins provides no advantage over primary amputation for patients with localized disease or regional metastases.[675] In a palliative setting, systemic chemotherapy offers a limited and brief response, although an extended response was observed with navelbine.[676,677] Disease stabilization with sunitinib has been described.[678]

Histologically, the more aggressive "proximal" type variant exhibits a distinct rhabdoid phenotype with a pattern of growth that is more sheetlike than nodular.[679] Nodular aggregates consist of medium-sized to large epithelioid and plump spindled cells with central necrosis and collagenization simulating granulomas or metastatic carcinoma (Fig. 60-30, *A*).[680] Immunohistochemically, tumor cells are commonly positive for keratin 8 and 19, EMA (see Fig. 60-30, *B*), vimentin, and CD34.[681,682] Tumor cells are typically diploid, although deletions of the long arm of chromosomes 22 and 1, monosomy 21, and isochromosome 8q as well as gains at 22q have been noted.[683-688] t(8;22)(q22;q11) and t(6;8)(p25;q11.2) have been reported in isolated cases of epithelial sarcoma.[689,690] As in malignant rhabdoid tumors, the majority of epithelioid sarcoma lose *SMARCB1,* which is located at 22q12, through homozygous deletion, although this loss may be less common in pediatric cases.[691-694] Epidermal growth factor receptor (EGFR) overexpression has been noted in epithelioid sarcoma, and one cell line derived from a recurrent malignant tumor demonstrates interleukin-6 secretion and receptor expression, suggesting autocrine activation.[695-697] In preclinical studies, EGFR modulation affected tumor cell proliferation and motility and combined EGFR and mTOR inhibition decreased tumor cell growth.[698] Autocrine MET activation by HGF production has been speculated based on detection of both proteins by immunohistochemistry.[538]

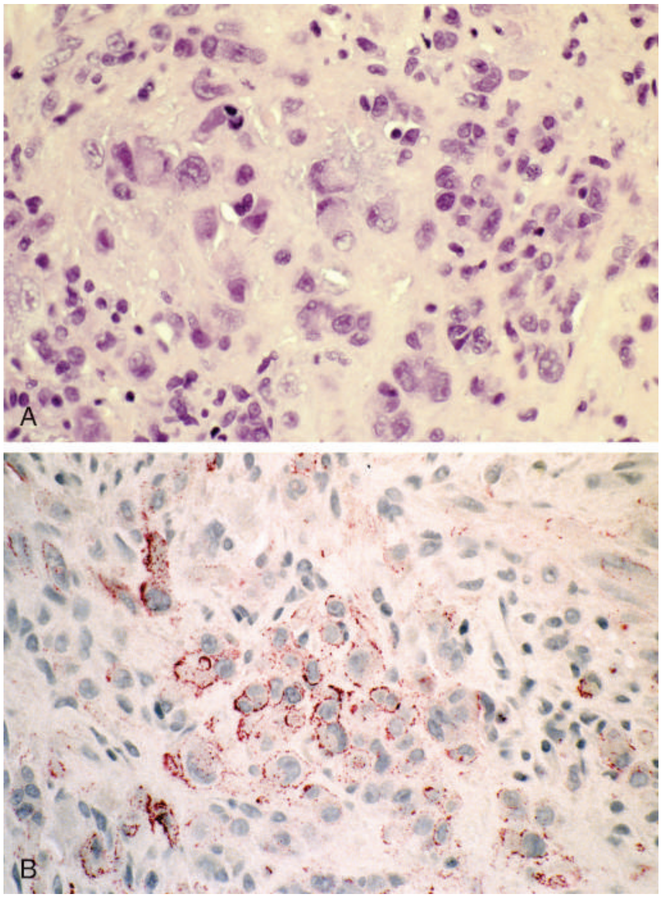

Figure 60-30 Epithelioid sarcoma. **A,** Granuloma-like cluster of large atypical cells (some with rhabdoid morphology), scattered inflammatory cells, and collagenization. **B,** Tumor cells are strongly immunoreactive for epithelial membrane antigen *(membranous pattern).*

Extraosseous Ewing Sarcoma

Although more commonly associated with an osseous origin, extraosseous Ewing sarcoma (peripheral primitive neuroectodermal tumor) can arise in many locations, including the small intestines, kidney, and spinal epidural space. Like its osseous counterpart, extraosseous Ewing sarcoma consists of undifferentiated small round cells with minimal neuronal differentiation. It is characterized by membranous immunoreactivity for CD99 and harbors rearrangement of the *EWSR1* gene on chromosome 22 with a variety of partner genes, but most commonly with *FLI1* on chromosome 11. Other partner genes include *ERG, ETV1, EIAF,* and *FEV. EWSR1* break-apart FISH can be diagnostic. Extraosseous Ewing sarcoma is treated similarly to the osseous form.[699,700] Given differences in treatment and prognosis, care should be made to distinguish central nervous system Ewing sarcoma from central primitive neuroectodermal tumors. For a more complete discussion of Ewing sarcoma see Chapter 61, "Ewing Sarcoma."

Gastrointestinal Stromal Tumor

Most commonly originating from the stomach or small intestine, GISTs are mesenchymal neoplasms that can develop throughout the gastrointestinal tract. Typically, GISTs occur in middle-aged to older adults; however, approximately 3% of GISTs are identified in patients younger than 21 years of age.[701,702] Congenital GIST has been reported.[703,704] In children, the majority of tumors are identified in girls. Although isolated GIST predominates, multifocal epithelioid GIST is associated with Carney triad and together with paraganglioma in Carney-Stratakis syndrome.[702] GIST is also associated with NF1 patients in whom small multifocal but indolent tumors tend to be located in the small intestine.[705] Pediatric GIST typically presents as gastrointestinal hemorrhage that can result in anemia. Although the majority of tumors identified in children are surgically resectable and associated with a good prognosis, GIST is frequently metastatic. The most common sites of metastases at the time of presentation or recurrence are the liver and omentum.[706]

The cell of origin for GIST is uncertain, but the observation that tumor cells have immunohistochemical[548] and

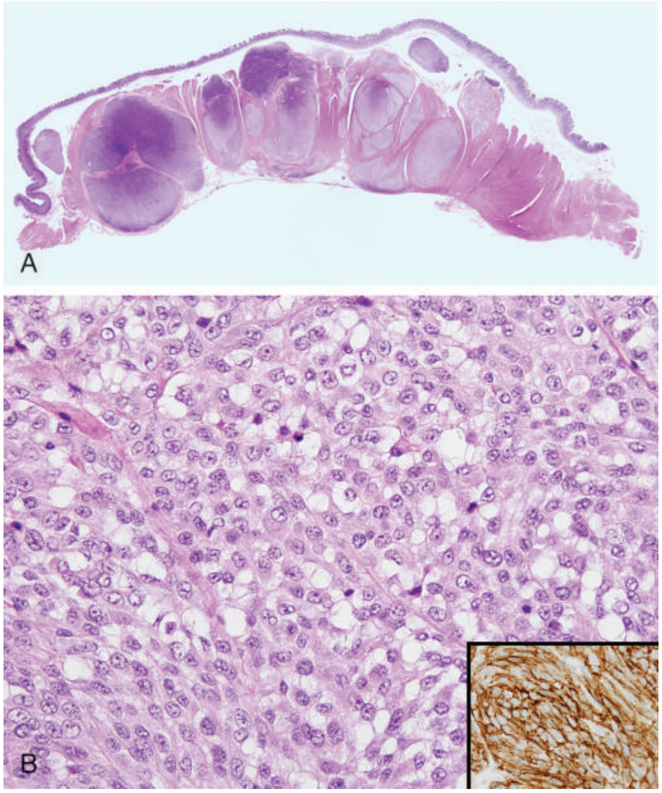

Figure 60-31 Gastrointestinal stromal tumor. **A,** Gastric antrum showing multifocal GISTs centered within the muscularis propria. **B,** Nests of tumor are composed of spindled and epithelioid cells, diffusely immunoreactive for *KIT (inset)*.

ultrastructural[707,708] similarities to the interstitial cells of Cajal led to the proposition that GIST derives from these cells.[707,708] Histopathologically, most GISTs are composed of spindled cells with blunt-ended, elongated nuclei and moderately abundant cytoplasm (Fig. 60-31). They resemble smooth muscle or peripheral nerve sheath tumors. Unlike these tumors, however, immunohistochemistry of GIST in adults and children almost uniformly demonstrates the presence of the receptor tyrosine kinase KIT (CD117) (see Fig. 60-31, *B inset*) and, less frequently, CD34.[709,710]

Several molecular features distinguish adult and pediatric GIST. Whereas GIST in adults is often associated with chromosomal losses of 1p, 14q, and 22q with additional chromosomal gains and losses in metastatic tumors, pediatric GIST typically lacks cytogenetic aberrancy.[711-713] GIST in adults is frequently associated with activating mutations identified in multiple regions of the stem cell factor (also known as mast cell growth factor) receptor *KIT*.[714-716] Mutations include in-frame deletions and amino acid substitutions. A significant fraction of tumors that lack *KIT* mutations harbor activating mutations in *PDGRFA*.[717] The ETS family transcription factor ETV1 is highly expressed in GIST and cooperates with activated KIT.[718] Strikingly, in pediatric GIST, *KIT* and *PDGFRA* are infrequently mutated.[702,719,720] GIST in children and young adults is more commonly associated with mutations that affect the succinate dehydrogenase (SDH) complex.[23,721] The SDH complex, located in the mitochondrial inner membrane, consists of four proteins and catalyzes the oxidation of succinate to fumarate in the citric acid cycle, and mutations significantly decrease complex activity.[24,722] Loss of SDH activity leads to accumulation of fumarate and succinate, which inhibits α-ketoglutarate–dependent processes, including histone demethylases and the TET family of 5-methylcytosine hydroxylases that may alter chromatin in tumors.[723] In addition, SDH loss can increase oxidative stress and promote DNA mutagenesis.[724] Mutations in *SDHB, SDHC,* and *SDHD* have been associated with GIST as well as paraganglioma and pheochromocytoma.[725-729] Mutation in *SDH* genes have been also associated with other tumors, including renal cell carcinoma. IGF1R is frequently expressed in *SDH* mutation–negative tumors, and IGF1 and IGF2 expression seems to correlate with disease-free survival.[730,731]

Historically, nonmetastatic GIST was managed surgically.[732] However, treatment with the KIT and PDGFR targeted inhibitor imatinib demonstrates a significant and durable response in a majority of patients harboring *KIT*- and *PDGFR*-activating mutations.[733,734] Although a significant fraction of tumors progress owing to acquired resistance to imatinib, they may respond to second-line treatment with sunitinib.[735,736] Consequently, *KIT* and *PDGF* genotyping is important in determining initial treatment. For localized tumors without *KIT* or *PDGF* mutation, surgical resection should be performed. For asymptomatic patients with unresectable or metastatic disease, frequent surveillance is reasonable, with resection reserved for disease progression or development of clinical symptoms.[737] In children, the demonstration of KIT activation in the absence of mutation suggests that KIT inhibition may be effective.[713]

Ectomesenchymoma

Ectomesenchymoma is a rare tumor that affects primarily young children. Histopathologically, ectomesenchymomas are composed of a mixture of embryonal rhabdomyosarcoma, ganglioneuroma, and other neuroectodermal or mesenchymal components.[738-740] These tumors are believed to derive from neural crest cells. Treatment of these tumors typically involves surgical resection followed by sarcoma- or rhabdomyosarcoma-directed chemotherapy.[739,741]

NEUROECTODERMAL TUMORS

Malignant Peripheral Nerve Sheath Tumors

MPNSTs are sarcomas that ultrastructurally and immunohistochemically demonstrate nerve sheath differentiation.[742] An origin from a nerve or within a benign nerve sheath tumor or ganglioneuroma as well as a history of NF1 are also important in the diagnosis of this tumor. Previously referred to as malignant schwannomas and neurofibrosarcoma, the term MPNST is preferred given the heterogeneity of tumor cell morphology. MPNSTs typically arise in the deep soft tissues of the extremities, head and neck, and trunk and may present as a mass or symptoms of nerve compression, including

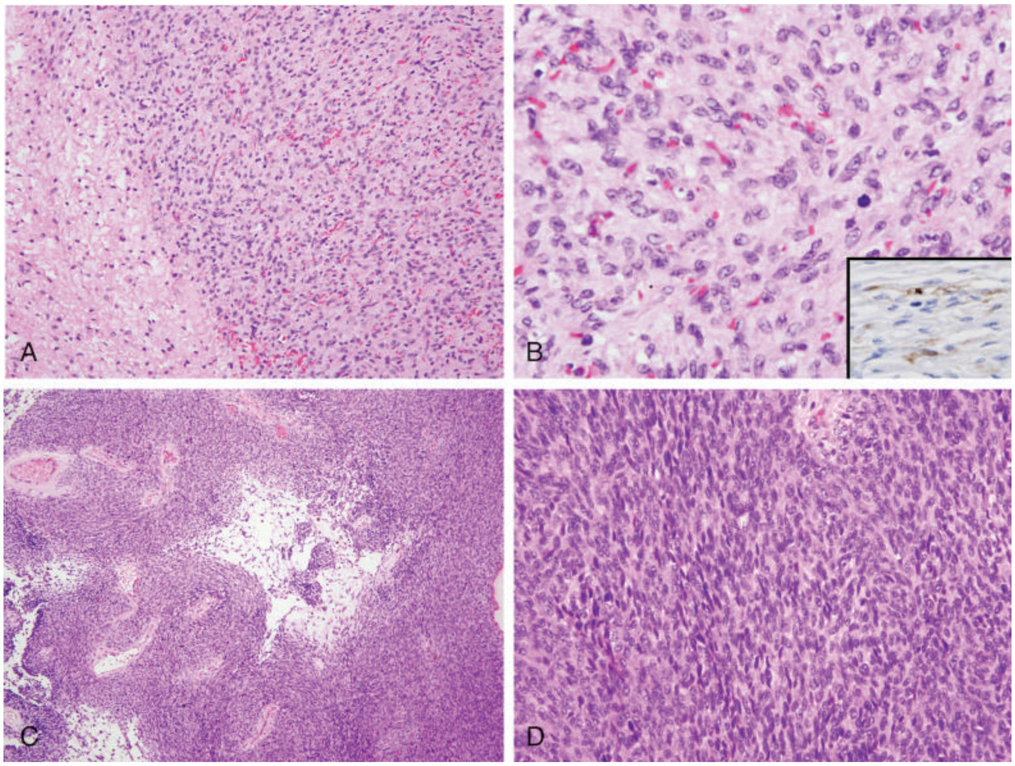

Figure 60-32 Malignant peripheral nerve sheath tumor. **A,** Low-grade MPNST showing a cellular area *(at right)* sharply demarcated from a less densely cellular component *(left)*. **B,** At higher magnification, low-grade MPNST showing mild atypia and occasional mitoses. Low-grade MPNST shows focal strong nuclear and cytoplasmic immunoreactivity for S100 protein *(inset)*. **C,** High-grade MPNST showing densely cellular spindled cell tumor. **D,** At higher magnification, tumor cells in high-grade MPNST are densely arranged and have hyperchromatic nuclei and scattered mitoses and apoptosis.

pain, dysesthesia, or motor disturbance.[742,743] Fifty to 80 percent of MPNSTs develop spontaneously. Patients with NF1 have a lifetime incidence of MPNSTs between 2% and 29%.[16,18,744-747] In a pediatric population, MPNSTs in NF1 patients tend to develop at an older age and tumors tend to be larger, less likely to be resectable, and less likely to respond to chemotherapy than those that develop spontaneously.[743] MPNST is associated with a 5-year OS of 40% to 50% and a PFS of 35% to 37%.[743,748] However, IRS grouping strongly predicts both OS and PFS with complete surgical resection associated with an OS of 80% at 10 years. Histologically, MPNST is composed of fascicles of spindled cells with oval to wavy, slender nuclei with tapering poles and a pale cytoplasm with a poorly defined border (Fig. 60-32).[742] Perivascular hypercellularity and abrupt changes from dense cellular areas to zones containing abundant myxoid matrix are features that suggest nerve sheath differentiation. Pleomorphic, hyperchromatic nuclei are frequently present. Mitoses are usually frequent except in low-grade tumors arising in preexisting neurofibromas in patients with neurofibromatosis (see Fig. 60-32, *A* and *B*). High-grade MPNSTs are densely cellular with frequent mitoses and areas of necrosis (see Fig. 60-32, *C* and *D*). MPNST with rhabdomyoblastic differentiation is referred to as malignant triton tumor and has a worse prognosis than the typical MPNST. Osteosarcomatous or glandular differentiation may also occur. Immunohistochemically, MPNST may show focal positivity for S100 protein, EMA, and glial fibrillary acidic protein (GFAP). For unresectable or metastatic disease or for large tumors, chemotherapy with doxorubicin and ifosfamide or ifosfamide alone can be of limited benefit.[743] Radiation therapy can be beneficial for higher-grade lesions and incomplete resections and is often administered concurrently with chemotherapy. MPNST in the context of NF1 tends to be more refractory to chemotherapy and more likely to recur locally.

The development of MPNST is associated with loss of the tumor suppressor *NF1* at 17q11.2, which encodes neurofibromin. Neurofibromin is a guanosine triphosphatase (GTPase)-activating protein that modulates RAS signaling.[749-753] MPNSTs also frequently harbor mutations of *TP53* and the *CDKN2A*/*CDK2AP2* (*p16*^{INK4a}/*p14*^{ARF}) locus affecting both the TP53 and RB pathways in 75% of tumors.[754] *CDKN2A* or *CDK2AP2* promoter inactivation by CpG island methylation may also downregulate expression.[755] Mice with homozygous *Tp53* and heterozygous *Nf1* deficiency develop predominantly MPNST and malignant triton tumor–appearing sarcomas, and these tumors demonstrate loss of heterozygosity at the *Nf1* locus.[756,757] Multiple signaling pathways appear to be involved in MPNST development. EGFR is consistently expressed in MPNST- and MPNST-derived cell lines, and 26% of MPNSTs demonstrate amplification of the *EGFR* locus.[758,759] *IGF1R* is amplified in 24% of tumors and expression correlates with survival.[760]

Enforced EGFR expression in transgenic mice results in Schwann cell hyperplasia with rare tumor development, whereas EGFR haploinsufficiency in *Nf1+/–*, *Tp53+/–* mice significantly reduces tumor formation.[761] Mutagenesis screening in mice identified Wnt/β-catenin as well as PI3K/AKT/mTor pathway alterations in MPNST.[762,763] PTEN, which modulates PI3K signaling, is involved in malignant transformation.[764]

Melanotic Neuroectodermal Tumor of Infancy

Melanotic neuroectodermal tumor (retinal anlage tumor, melanotic progonoma) is a dysembryoplastic tumor that recapitulates embryonic retinal development. Most cases occur in the head and neck region, particularly in the maxilla, and usually affect male children younger than 1 year of age. The tumors are typically benign but grow rapidly, invade locally, and may metastasize in about 5% of cases.[765] Although complete surgical resection is required for cure, chemotherapy has been shown to decrease tumor mass, thus improving resectability.[766,767] Local recurrence after resection is common, with virtually all recurrences within 4 months and justifying close follow-up.[768] Balancing the desire for negative margins with disfigurement supports a staged surgical approach, and multiple resections may be required to ultimately establish disease control.

The tumor is classified in the family of neuroblastic tumors, and rare cases are associated with elevated urinary levels of vanillylmandelic acid. The histopathology is characteristically biphasic with a component of neuroblast-like cells with neuropils arranged in nests and an epithelioid melanocyte-like component containing melanin (Fig. 60-33). The melanocyte-like cells are usually arranged at the periphery of the neuroblastic-like cells, forming pseudoglandular or pseudoalveolar structures in a densely fibrous stroma. Both cellular components are immunoreactive with neuroectodermal markers such as synaptophysin, GFAP, and Leu7. Melanocyte-like cells are also immunoreactive with HMB45 and cytokeratins.

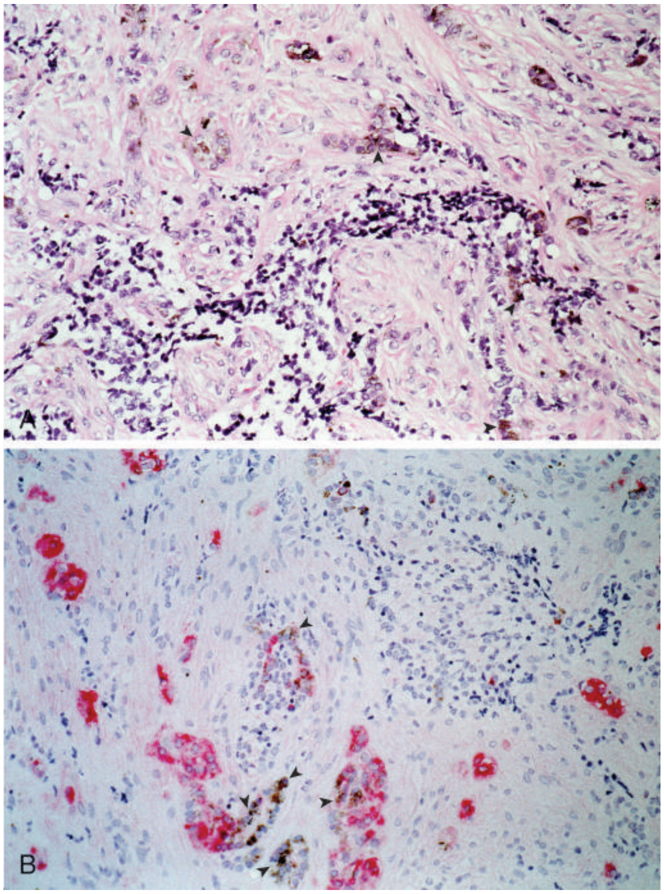

Figure 60-33 Retinal anlage tumor (progonoma). **A,** Biphasic tumor with a component of neuroblastic-like cells with neuropil arranged in nests and an epithelioid melanocyte-like cell component containing melanin *(arrowheads)*. The melanocyte-like cells arranged at the periphery of the neuroblastic-like cells form pseudoglandular or pseudoalveolar structures in a densely fibrous stroma. **B,** Strong cytokeratin immunoreactivity in melanocyte-like cells *(red)*. The dark cytoplasmic granules represent melanin pigment *(arrowheads)*.

UNDIFFERENTIATED TUMORS

Undifferentiated Pleomorphic Sarcoma and Undifferentiated Round Cell and Spindle Cell Sarcoma

Advances in immunophenotyping, microscopy, and molecular-based techniques have resulted in improved classification of soft tissue tumors. Historically, for the purposes of therapeutic trials in childhood cancers, undifferentiated sarcoma had been grouped with rhabdomyosarcoma. However, the application of MyoD1 and myogenin immunohistochemistry enabled segregation of rhabdomyosarcoma from undifferentiated sarcoma. A similar reclassification also occurred for adult undifferentiated sarcomas. Many of the tumors previously described as malignant fibrous histiocytoma have been reclassified to specific categories on the basis of immunohistochemistry, electron microscopy, and molecular genetics.[769-771] However, as a diagnosis of exclusion, undifferentiated sarcomas represent a collection of tumors that lack identifiable morphologic, immunohistochemical, or genetic changes, thus permitting classification as a specific subtype of sarcoma using currently available technologies (Fig. 60-34). Classification of these otherwise undifferentiated tumors rests exclusively on their histology, including undifferentiated round cell and spindle cell sarcoma and undifferentiated pleomorphic sarcoma.

In infants younger than 1 year of age, undifferentiated sarcoma constitutes the most common nonrhabdomyosarcoma malignant mesenchymal tumor. Surgery and chemotherapy result in a 10-year OS of 75%.[8] Undifferentiated pleomorphic sarcoma constitutes a common soft tissue tumor of older adults, with a peak incidence in the seventh decade, and rarely occurs in children or adolescents.[772] A high-grade malignancy, this tumor demonstrates a significant incidence of local and distant recurrence. Pulmonary and lymph node metastases are most common. In a trial of docetaxel and gemcitabine compared with docetaxel alone in metastatic sarcoma, undifferentiated pleomorphic sarcoma was among the most responsive tumor type and demonstrated superior response to both agents in combination.[101]

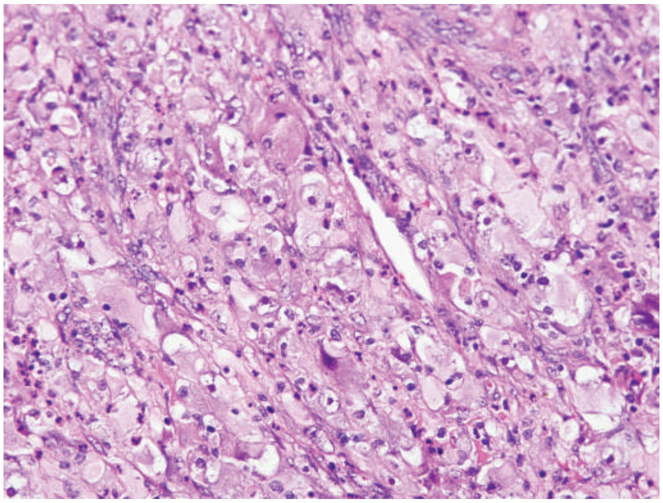

Figure 60-34 High-grade undifferentiated sarcoma. Undifferentiated, pleomorphic sarcoma composed of large highly anaplastic tumor cells. Immunohistochemistry, electron microscopy, and cytogenetics defied further classification.

Pediatric undifferentiated sarcomas may express vimentin, KIT, and VEGF.[773] Hierarchical clustering of adult STS based on messenger RNA expression array profiling revealed an undifferentiated sarcoma class, distinct from, among other tumors, fibrosarcoma and liposarcoma.[542] Expression analyses performed by other groups have also clustered undifferentiated sarcomas but with intermingling of liposarcoma and leiomyosarcoma to varying degrees.[774,775] Cytogenetic studies have also demonstrated that a subset of undifferentiated sarcoma share some features with liposarcoma, but tumors with 12q14-15 amplification, which includes MDM2 and CDK4, are now classified as dedifferentiated liposarcoma.[61,776] Murine modeling suggests that some undifferentiated pleomorphic sarcomas exist on a developmental continuum with embryonal rhabdomyosarcoma and arise from muscle satellite cells.[777]

Undifferentiated round cell and spindle cell sarcomas are occasionally characterized by *EWSR1* translocations and fusion with genes other than those of the ETS transcription factor family typical in Ewing sarcoma. Gene partners include *PATZ1, POU5F1 (OCT3/4), SMARCA5, NFATC2,* and *SP3*.[778] Although the involvement of *EWSR1* as a translocation partner in these tumors suggests that they constitute Ewing sarcoma variants, genomic targeting of these fusions would be expected to differ from the ETS transcription factor containing fusions characteristic of Ewing sarcoma.[779] Other translocations include *CIC-DUX4* and *BCOR-CCNB3*. WNT signaling seems to play a central role in undifferentiated sarcoma development. DKK1, the secreted inhibitor of WNT signaling, is expressed in undifferentiated sarcoma, and it inhibits differentiation by blocking Wnt2/β-catenin signaling.[780] Conversely, treatment of an undifferentiated sarcoma cell line with either exogenous Wnt2 or Wnt5a induced markers of adipogenic or osteogenic differentiation. JUN deregulation may also play a role in undifferentiated sarcoma. *JUN* and *JNK* can be amplified in undifferentiated sarcoma, and JUN can inhibit adipogenic differentiation.[781]

CHAPTER 61

Ewing Sarcoma

Steven G. DuBois, Holcombe E. Grier, and **Stephen L. Lessnick**

CHAPTER OUTLINE

EPIDEMIOLOGY

BIOLOGIC FEATURES
- Chromosomal Rearrangements in Ewing Sarcoma
- The Cloning of EWS/FLI
- EWS/FLI and Other TET/ETS Fusions in Ewing Sarcoma
- Ewing Sarcoma Cell of Origin
- EWS/FLI Target Genes
- Cooperative Pathways in Ewing Sarcoma Oncogenesis
- Apoptotic Pathways in Ewing Sarcoma
- Biological Features Summary

CLINICAL PRESENTATION AND DIAGNOSIS
- Clinical Presentation
- Imaging Features
- Pathologic Diagnosis

PROGNOSTIC FACTORS

TREATMENT OF PATIENTS WITH NONMETASTATIC EWING SARCOMA
- Local Control
- Systemic Treatment with Chemotherapy
- Management of Tumors Arising at Special Sites
- Summary of Outcomes for Patients with Nonmetastatic Ewing Sarcoma

TREATMENT OF PATIENTS WITH METASTATIC EWING SARCOMA
- Systemic Therapy
- Role of Surgery and Radiation in Patients with Metastatic Disease
- Role of High-Dose Therapy with Hematopoietic Stem Cell Rescue for Metastatic Disease
- Summary of Outcomes for Patients with Metastatic Ewing Sarcoma

RECURRENT EWING SARCOMA
- Location and Timing of Disease Recurrence
- General Approach to Patients with Recurrent Ewing Sarcoma
- Systemic Therapies for Recurrent Ewing Sarcoma
- Role of Surgery and Radiation for Recurrent Ewing Sarcoma
- Role of High-Dose Therapy with Hematopoietic Stem Cell Rescue for Recurrent Disease
- Outcomes for Patients with Recurrent Ewing Sarcoma

LATE EFFECTS IN PATIENTS TREATED FOR EWING SARCOMA

FUTURE DIRECTIONS

In 1921 James Ewing described the cancer that came to carry his name: a primary bone tumor composed of small round blue cells and devoid of the malignant osteoid that characterizes osteosarcoma.[1] Subsequently, pathologists described other clinicopathologic entities initially thought to be distinct, such as peripheral primitive neuroectodermal tumor (PNET) of bone or soft tissue or the Askin tumor of the chest wall.[2] However, biologic study and clinical responses to chemotherapy have now linked these tumors into one entity or family of tumors, a grouping that also includes extraosseous Ewing sarcoma. Commonly used terms for this tumor include Ewing sarcoma, Ewing tumors, and Ewing sarcoma family of tumors. In this chapter the World Health Organization–approved term, Ewing sarcoma, is generally used. When appropriate, specific characteristics that differentiate Ewing sarcoma, PNET, and Askin tumors are described.

The chapter begins with a discussion of the epidemiology of Ewing sarcoma. Next, the current understanding of the cellular and molecular features of these tumors is reviewed. An overview of the clinical presentation and prognostic features of patients with this disease are presented. This overview is followed by a discussion of the management of patients with Ewing sarcoma. The chapter concludes with a review of the late effects seen in patients treated for these tumors.

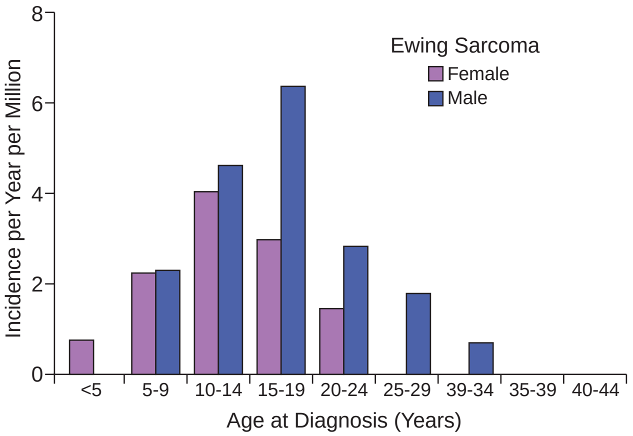

Figure 61-1 Incidence of Ewing sarcoma for male and female subjects according to age at initial diagnosis. *(From Mascarenhas L, Siegel S, Spector L, et al., Malignant bone tumors. In Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and aurvival 1975-2000. Bleyer A, O'Leary M, Barr R, and Ries L, Editors. 2006,* National Cancer Institute: *Bethesda. p. 98–109.)*

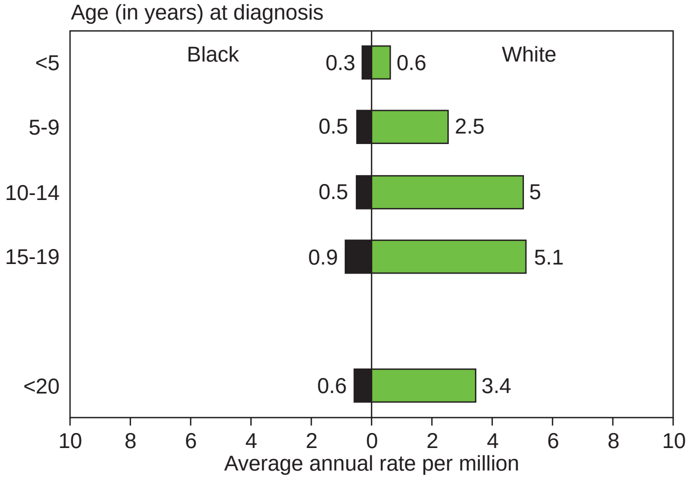
EPIDEMIOLOGY

Ewing sarcoma is the second most common type of primary bone cancer in the United States and Europe, accounting for approximately 25% to 34% of malignant bone tumors.[3-5] Approximately 250 new cases of Ewing sarcoma are diagnosed in the United States each year.[4,5] In the United States Ewing sarcoma has had a relatively stable average incidence of 2.5 to 3 cases per million per year from 1975 to 2000.[4,6] A similar age-adjusted incidence has been noted in Europe.[3] As shown in Figure 61-1, the peak incidence occurs during adolescence, with an average incidence of 4.6 cases per million per year for the 15- to 19-year age range.[4] Younger children are affected less frequently, and the disease is distinctly uncommon in adults older than 35 years of age. A male predominance has been noted, with a male-to-female ratio of approximately 1.25 : 1.[5,7] However, one study reported a female predominance in patients younger than 3 years of age at initial diagnosis.[8] There is no seasonal variation in the appearance of this disease.[7,9]

The incidence of Ewing sarcoma varies markedly among races and countries, with the highest frequency reported from Australia and Sao Paolo, Brazil.[10] People of African ancestry appear to have the lowest incidence of this disease. Figure 61-2 demonstrates the dramatically lower incidence of these tumors in the U.S. African-American/Black population.[55] A similar low incidence in sub-Saharan Africa has been reported and suggests a possible genetic difference in the risk of developing Ewing sarcoma.[10,11] Patients of African ancestry with Ewing sarcoma have higher rates of soft tissue tumors and an older age distribution compared with patients of European ancestry, indicating that racial differences in this disease extend beyond differences in incidence.[12] Ewing sarcoma also appears to be uncommon in people of East Asian ancestry, based on data from China, Japan, and Thailand.[10,13,14] Data from the Middle East, North Africa, and the Indian subcontinent suggest that Ewing sarcoma is at least as common in these populations as in people of European ancestry.[10,15-17] In small studies from Kuwait and Bombay, for example, Ewing sarcoma was identified as the most common primary malignant bone tumor.[16,17]

Based on these geographic differences in the incidence of Ewing sarcoma, several groups have investigated the genetic epidemiology of this disease. One group reported differences between African and European populations in the number of Alu repeat sequences in intron 6 of the *EWSR1* gene, upstream of the breakpoint region involved in translocations at this locus seen in most cases of Ewing sarcoma.[18] Two studies further focused on this possibility that differences in the incidence of Ewing sarcoma may be due to differences in polymorphisms in the *EWSR1* locus that could result in different rates of translocation.[19,20] Both studies each identified a different single nucleotide polymorphism with low-level statistical association with Ewing sarcoma, although the effect of each polymorphism on the risk of Ewing sarcoma was small. Another study investigated the incidence of other tumors that harbor *EWSR1* translocations across racial groups and observed higher rates of desmoplastic small round cell tumor in the U.S. African-American population compared with the U.S. European-American population.[21] This finding of higher rates of an *EWSR1*-associated tumor in a population with a lower rate of Ewing sarcoma provides additional evidence that differential susceptibility to translocation at the *EWSR1* locus does not account for racial differences in the incidence of Ewing sarcoma. More recently, a genome-wide association study identified and validated polymorphisms in three loci, 1p36, 10q21, and 15q15, associated with increased risk of



*Adjusted to the 1970 US standard population

Figure 61-2 Incidence of Ewing sarcoma by age according to race, demonstrating the marked rarity of the disease in the United States African-American/Black population. *(From Gurney JG, Swensen AR, Bulterys M: Malignant bone tumors, in cancer incidence and survival among children and adolescents: United States SEER Program 1975-1995. Ries LAG, Smith MA, Gurney JG, et al, editors.* National Cancer Institute, SEER Program, *NIH Pub. No. 99-4649, Bethesda, MD, 1999, p. 99–110.)*

Ewing sarcoma. These risk variants are present at lower frequencies in African populations, providing one potential explanation for the lower rates of Ewing sarcoma in this population.[22]

The etiology of Ewing sarcoma remains largely obscure. These tumors are not generally believed to be familial, although rare cases of sibling pairs with Ewing sarcoma have been reported.[23-25] First- and second-degree relatives of patients with Ewing sarcoma do not appear to have an increased overall risk of cancer, although a higher rate of stomach cancer, melanoma, renal cancer, and brain tumors has been reported.[26,27]

Patients with Ewing sarcoma appear to have an increased incidence of specific congenital anomalies. The most consistent finding has been an association between Ewing sarcoma and congenital hernias, particularly inguinal hernias.[28-30] A pooled analysis of the available literature has confirmed this association, with an odds ratio of developing Ewing sarcoma of 2.8 for children with congenital hernias compared with children without congenital hernias.[31] Whether a common hormonal or environmental mechanism underlies the development of both congenital hernias and Ewing sarcoma remains unclear. Patients with Ewing sarcoma have also been noted to have an increased incidence of bone anomalies, particularly rib and vertebral anomalies.[30,32,33] Other congenital anomalies, including cataracts and genitourinary anomalies, have been reported in patients with Ewing sarcoma.[30,32,34] These anomalies occur at a low incidence in these patients and without a consistent pattern, suggesting that their occurrence with Ewing sarcoma may be coincidental.

Various parental exposures have been associated with the risk of developing Ewing sarcoma. The most consistent finding has been an association between parental farm exposure around the time of conception through birth and the subsequent development of Ewing sarcoma. This association has been reported in a series of case-control studies and affirmed in a meta-analysis, with an increased risk if either parent was involved in farming.[28,35-38] Specific exposures related to agricultural work that have been suggested as driving this increased risk include parental fertilizer, pesticide, solvent, and wood dust exposure.[36,37,39] Less consistently reported associations include an increased risk of Ewing sarcoma with parental cigarette smoking and parental occupation in manual labor.[28,36] Family income does not appear to be associated with the risk of Ewing sarcoma.[28,37]

Additional attention has focused on features of physical growth and development that might distinguish patients with Ewing sarcoma. Differences in birth weight between patients with Ewing sarcoma and controls have not been observed.[40] Given its peak incidence during adolescence, some groups have investigated differences in the onset of puberty between patients with Ewing sarcoma and controls. One group reported that boys with Ewing sarcoma began shaving earlier than boys without Ewing sarcoma.[29] Other differences related to development of secondary sex characteristics have not been observed.[29,40] At the time of diagnosis, patients with Ewing sarcoma do not seem to be taller than their peers.[40-42]

Several viruses have been suggested as playing a role in the pathogenesis of Ewing sarcoma. One group reported that the adenovirus *E1A* gene could specifically induce the chromosomal translocation characteristic of these tumors.[43] Follow-up studies failed to corroborate this finding.[44-47] Based on increased Epstein-Barr virus titers in patients with Ewing sarcoma, other groups evaluated Ewing tumors for Epstein-Barr virus infection and found no viral involvement.[48,49] Both BK and SV40 viral sequences have been variably identified in cases of Ewing sarcoma, but the functional importance of these findings remains unknown.[50-52]

Ewing sarcoma rarely develops as a second malignancy. Several case reports describe the development of Ewing sarcoma years after the successful treatment of children with a range of hematologic malignancies and solid cancers.[53-58] More formal studies indicate that Ewing sarcoma as a second malignancy occurs only infrequently. In a population-based study, 2.1% of all Ewing sarcoma cases arose as second malignancies.[59] In a large institutional review, only 1.3% of second malignancies following treatment of pediatric cancer were Ewing sarcoma or PNET.[60] Several large series of patients with secondary bone sarcomas have reported only a small number of patients with Ewing sarcoma.[61-64] These secondary Ewing tumors do not appear to be radiation-related.[59] In addition, the wide range of primary malignancies described in these patients suggests that these tumors do not arise as part of a specific cancer predisposition syndrome.

BIOLOGIC FEATURES

Chromosomal Rearrangements in Ewing Sarcoma

In the mid-1980s the presence of a recurrent reciprocal chromosomal translocation, t(11;22)(q24;q12), was reported in Ewing sarcoma tumors and cell lines.[65,66] The same translocation was also identified in PNET, supporting the hypothesis that these two tumors represented the same disease exhibiting varying levels of differentiation along a neuronal pathway.[67] Subsequent studies demonstrated that t(11;22)(q24;q12) was present in approximately 83% of Ewing sarcomas.[68]

The early analysis of translocations in Ewing sarcoma demonstrated that the derivative chromosome 22 was always maintained as these tumors and cell lines undergo clonal evolution, whereas the derivative chromosome 11 could be lost.[66] This indicated that the “22;11” derivative is the key chromosomal abnormality, whereas the reciprocal “11;22” is unnecessary. The t(11;22)(q24;q12) is a tumor-specific or somatic mutation because it is not found in the germline DNA of patients.[66]

In addition to the t(11;22)(q24;q12) rearrangement (and related translocations with similar molecular consequences, discussed later), other chromosomal abnormalities have also been reported in Ewing sarcoma.[66,69-75] A careful analysis of these sometimes complex karyotypes has revealed a small group of recurrent, nonrandom chromosomal abnormalities. Gains (usually trisomies) of chromosome 8 may be observed in up to 50% of cases, and gains of chromosomes 12 and 1q are seen in approximately 25% of cases.[69,73,74,76,77] Gains in chromosome 20 have also been reported in 10% to 20% of cases.[78] Interestingly, a chromosomal translocation that is unrelated to the t(11;22)(q24;q12) has been observed in approximately 20% of cases: der(16)t(1;16).[69,73,74,76,77] This translocation is often found as an unbalanced rearrangement and thus results in partial gains (trisomies and occasionally tetrasomies) of 1q and losses (monosomies) of 16q.[69,73,74,76,77] The breakpoints of this translocation appear to be variable and range from q11 through q32 on chromosome 1 and from q11.1 through q24 on chromosome 16.[69,73,74,76,77] This suggests that the translocation does not alter particular target genes at the breakpoint but rather introduces gains of 1q and losses of 16q. Finally, losses at 1p36 have also been observed.[75] More recent high-resolution copy number studies have identified copy number alterations in specific genes or regions of the genome, although the role of specific genomic gains or losses has yet to be determined.[79-82] There has also been a report of genomic instability, as measured by microsatellite instability and loss of heterozygosity, in Ewing sarcoma.[83] This finding, however, is somewhat controversial, insofar as a second group was not able to replicate the microsatellite instability findings.[84]

The Cloning of EWS/FLI

A major advance in the understanding of the pathogenesis of Ewing sarcoma occurred when the breakpoint of the (11;22)(q24;q12) translocation was cloned in 1992.[85] The translocation breakpoint was localized roughly in the middle of two genes: *EWSR1* and *FLI1*. *EWSR1* had not been previously identified and so was named on the basis of its involvement in the Ewing sarcoma translocation breakpoint (*Ew*ing *s*arcoma *r*earrangement domain *1*).[85,86] *FLI1* had been previously identified in mice as the *F*riend *L*eukemia Virus *i*ntegration site.[87] As a result of the translocation event, these two genes become fused and the expressed transcript encodes the EWS/FLI fusion protein (Fig. 61-3).[85]

Wild-Type EWS Protein

EWSR1 encodes the EWS protein (see Fig. 61-3).[85] Wild-type EWS contains 656 amino acids and appears to be ubiquitously expressed.[85,88,89] EWS is primarily localized to the nucleus,[90-92] although it has also been detected in the cytoplasm[93] and on the cell surface.[94] The amino terminus of EWS (sometimes referred to as NTD-EWS) contains 285 amino acids consisting of 31 pseudorepeats rich in tyrosine, glutamine, serine, threonine, glycine, alanine, and proline.[85] This region bears some similarity to the carboxyl-terminal domain (CTD) of RNA polymerase II.[85] This similarity suggested that the region could modulate RNA transcription. The carboxyl terminus of EWS contains an RNA recognition motif (an RRM domain), as well as three arginine-glycine-glycine (RGG) domains that are often found in RNA binding proteins. Indeed, it has been demonstrated, in vitro, that EWS can bind to RNA.[89,95] These findings suggest that wild-type EWS may be involved in RNA transcription or processing. The carboxyl-terminal region also contains a potential C_2C_2 zinc finger of uncertain significance.[96] There is evidence that EWS may undergo posttranslational modifications, but the significance of these alterations is not well understood.[94,95,97-100]

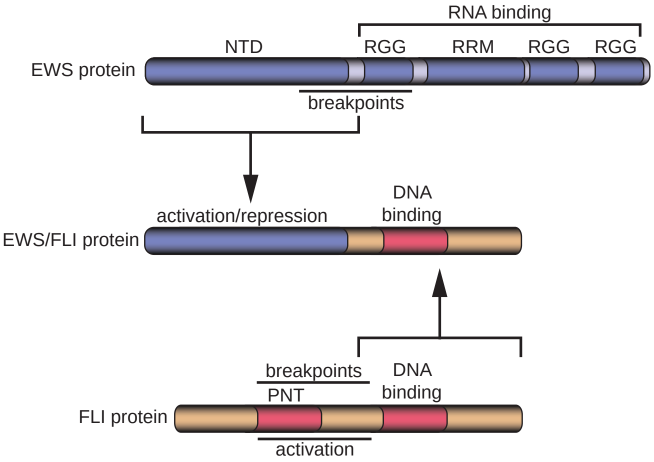


Figure 61-3 Fusion of EWS and FLI produces the EWS/FLI protein. Wild-type EWS is characterized by an amino-terminal domain *(NTD)*, along with three RGG regions and an RNA recognition motif *(RRM)* that confer RNA-binding properties to the protein. Wild-type FLI contains a pointed domain *(PNT)* that overlaps with a transcriptional activation domain and an ETS-type DNA-binding domain. The translocation breakpoint regions of each protein are shown. After a translocation event, EWS/FLI is formed. EWS/FLI maintains the NTD of EWS (which functions as both a strong transcriptional activation domain and a transcriptional repression domain in this context), and the DNA-binding domain of FLI.

EWS is closely related to two additional sarcoma-associated translocation partners, TLS (*t*ranslocated in *l*ipo*s*arcoma; also called FUS) and TAF15 (also known at $TAF_{II}68$, TAF2N, and RBP56), as well as to a *Drosophila melanogaster* protein named cabeza (also known as SARFH; originally called P19).[96,101-104] TLS was first identified in human myxoid liposarcoma in the context of the t(12;16)(q13;p11) translocation, which encodes a TLS/CHOP fusion protein (Table 61-1).[102,104] TAF15 is a member of the TFIID general transcription complex.[101] It is found fused to NR4A3 (also called CHN, TEC, CSMF, or NOR1) in extraskeletal myxoid chondrosarcomas and to ZNF384 (also called CIZ or NMP4) in acute leukemias (see Table 61-1).[105-107] TAF15 also has significant homology and domain organization to EWS and TLS.[101,103] The three human proteins are sometimes described as the TET family of proteins (*T*LS, *E*WS, *T*AF15) or the FET family (*F*US, *E*WS, *T*AF15). Although the normal function of these proteins is not completely understood, some evidence suggests that they may be involved in RNA splicing, gene expression, microRNA processing, and formation of RNA-containing intracellular granules.[90,101,108-125] Interestingly, constitutional mutations in TLS result in familial amyotrophic lateral sclerosis (ALS), and mutations in TAF15 may also be associated with the disease.[126,127]

Wild-Type FLI Protein

FLI is a member of the ETS family of transcription factors.[128] This family is defined by the presence of an ETS type DNA-binding domain and consists of 27 different members in humans.[129] As with most transcription

factors, ETS family members have a modular architecture with separate domains that contribute DNA binding and transcriptional functions.[130] The DNA-binding ETS domain of FLI is present in the carboxyl-terminal portion of the protein (see Fig. 61-3).[128] Most ETS family members (including FLI) bind to sequences containing a GGAA or GGAT core sequence.[129,130] In addition to DNA-binding function, FLI contains two separate transcriptional activation domains, one in the amino terminus and a second in the carboxyl terminus (distal to the ETS DNA-binding domain; see Fig. 61-3).[131] Wild-type FLI also contains a PNT (pointed) domain in the amino terminal portion of the protein.[132] PNT domains are thought to mediate protein-protein interactions.[133]

The normal role of FLI appears to be primarily in the hematopoietic lineage, where it regulates megakaryocytic development.[134,135] Knockout of murine Fli-1 results in abnormal megakaryocytic differentiation and a loss in vascular integrity that results in embryonic lethality from central nervous system hemorrhage.[136,137] Hemizygous deletion of FLI is found in patients with Paris-Trousseau or Jacobsen thrombocytopenia syndromes.[136,138,139] FLI also appears to be important for vascular development in the mouse and zebrafish.[136,140] FLI is also expressed in neural crest–derived mesenchyme in both the mouse and quail.[141,142] This finding is particularly interesting in light of the neural crest phenotype of Ewing sarcoma.

FLI itself can function as an oncogene, at least in the hematopoietic context. Indeed, the murine *Fli* locus was first defined as a predominant *F*riend *mu*rine *l*eukemia *v*irus (F-MuLV) insertion site.[87] Thus insertion of F-MuLV at the *Fli* locus results in upregulation of the *Fli* gene and subsequent development of erythroleukemia.[87,128] The oncogenic activity of FLI appears to be limited to the hematopoietic system as introduction of the protein into other models of oncogenesis, such as the NIH3T3 cell model, does not result in the transformed phenotype.[90]

EWS/FLI and Other TET/ETS Fusions in Ewing Sarcoma

EWS/FLI consists of the amino terminus of EWS fused, in frame, to the carboxyl terminus of FLI (see Fig. 61-3).[85] The EWS portion retained in the fusion contains the pseudorepeat domain that harbors a strong transcriptional activation function as well as a transcriptional repression function.[85,90,119,143] The RNA-binding domain of EWS is lost in the fusion protein and instead is replaced by the portion of FLI that contains its ETS DNA-binding domain.[85]

EWS/FLI functions as an oncoprotein. EWS/FLI can induce NIH3T3 cells (an immortalized mouse fibroblast cell line) to exhibit both anchorage independent growth and growth as tumors when injected subcutaneously into immunodeficient mice.[144-146] Conversely, blockade of EWS/FLI expression or function (via antisense RNA, dominant-negative blocking alleles, or RNA interference) causes Ewing sarcoma cells to lose their transformed phenotype.[147-155] These data demonstrate that EWS/FLI expression is required for the oncogenic phenotype of Ewing sarcoma. Interestingly, it has been reported that after therapy-induced neural differentiation of Ewing sarcoma, EWS/FLI expression may also be lost.[156] Although these data support an important role for EWS/FLI expression in Ewing sarcoma proliferation and transformation, they do not address whether EWS/FLI formation is the first step in Ewing sarcoma development or whether other oncogenic events occur first and are followed by EWS/FLI formation.

There are three main consequences of the t(11;22)(q24;q12) rearrangement. First, it places the transcriptional regulation of the EWS/FLI fusion under the control of the *EWSR1* promoter. This is important because the activity of the *FLI1* promoter is limited to hematopoietic (and perhaps neural crest) lineages, whereas the *EWSR1* promoter appears to be active in most, if not all, cell types (see previous sections). Second, the translocation results in a loss of one wild-type *EWSR1* allele and one wild-type *FLI1* allele. Loss of one *FLI1* allele is probably of no consequence because wild-type *FLI1* is not expressed in Ewing sarcoma.[155] Whether loss of one *EWSR1* allele is important in Ewing sarcoma development is not known. The third consequence of the translocation is that it creates the EWS/FLI fusion protein. This is important because although EWS/FLI functions as an oncoprotein, neither wild-type EWS nor wild-type FLI could induce transformation of NIH3T3 cells, thus demonstrating a gain of function for the EWS/FLI fusion.[90] Structure-function analyses of EWS/FLI demonstrated that both the amino terminal EWS domain and the ETS DNA-binding domain of FLI were required for oncogenic transformation of NIH3T3 cells and Ewing sarcoma cells.[143,144] These results indicate that the fusion protein functions as an aberrant transcription factor. Comparisons of EWS/FLI with wild-type FLI demonstrated that the EWS domain included in the fusion protein could function as a much stronger transcriptional activation domain than the domain of FLI that was lost in the fusion.[90] These results suggested that EWS/FLI induced oncogenic transformation by binding to target genes through its ETS DNA-binding domain and upregulating the expression of those genes through its EWS domain.

The mechanisms by which the EWS portion of the fusion functions as a transcriptional activation domain are only now beginning to be understood. Because wild-type EWS has been shown to interact with TFIID, RNA polymerase II, or the p300/CBP coactivators, it appears likely that these interactions are also important for EWS/FLI function.[109,111,116,117] RNA helicase A (RHA) has also been shown to be important for the transcriptional activity of EWS/FLI.[157] Thus RHA may also function as a coactivator for gene expression mediated by the fusion protein.

More recently, it has been appreciated that EWS/FLI also functions as a transcriptional repressor. For example, analysis of the transcriptional program triggered by EWS/FLI in Ewing sarcoma cells has revealed that more genes are downregulated by the fusion than are upregulated.[152,155] Additional analysis has demonstrated that EWS/FLI functions as a direct transcriptional repressor at some target genes, like *LOX* and *TGFBR2*.[143,158] The mechanism of repression appears to be through binding of a transcriptional corepressor complex called NuRD, that includes nucleosome remodeling function, as well as histone deacetylase and histone lysine-specific demethylase activities.[143] Both transcriptional activation and repression functions are required for the oncogenic activity of EWS/FLI in Ewing sarcoma cells.[143]

Analysis of EWS/FLI binding sites in the human genome revealed that the fusion protein binds to sites that contain "classic" ETS-type high-affinity sequences (e.g., ACCGGAAGTG).[159-161] However, a more interesting and unusual finding was that EWS/FLI was also found to bind to GGAA-containing microsatellite sequences.[159-162] EWS/FLI binds to these microsatellites and uses them as response elements to activate the expression of target genes, and the transcriptional function is proportional to the length of the microsatellite.[159,162,163] This raises the intriguing possibility that polymorphisms in GGAA-microsatellites associated with key EWS/FLI target genes (e.g., *NR0B1, CAV1,* or *GSTM4*) may alter susceptibility to Ewing sarcoma or perhaps outcome in patients with the disease.[162,164,165] It has also been suggested that the lack of GGAA-microsatellites near critical EWS/FLI target genes, such as *NR0B1*, in organisms other than humans might be the reason that only humans develop Ewing sarcoma.[159,162]

In addition to EWS/FLI, other less frequent Ewing sarcoma translocation breakpoints were cloned and revealed a very similar structural organization (see Table 61-1). As described, approximately 83% of Ewing sarcoma tumors contain an (11;22)(q24;q12) translocation.[66-68] Approximately 10% of cases demonstrate an alternate translocation, t(21;22)(q22;q12).[166] Cloning of the breakpoint of this rearrangement revealed that EWS was fused, in frame, to another member of the ETS family, ERG.[166] As in the case of EWS/FLI, the EWS/ERG fusion contains the amino terminus of EWS fused to the carboxyl terminus of ERG, which harbors its ETS DNA-binding domain.[166] Interestingly, the ETS DNA-binding domains of FLI and ERG are 98% identical at the amino acid level.[166,167] Subsequent investigations demonstrated that EWS/ERG also functioned as an oncoprotein in the NIH3T3 cell model.[146,168] In subsequent years additional translocations were identified in Ewing sarcoma, including a t(7;22)(p22;q12), t(17;22)(q12;q12), and t(2;22)(q33;q12).[169-172] Cloning of transcripts from these translocations demonstrated that in each case EWS was fused to another member of the ETS family.[169-172] Currently, five EWS/ETS fusions have been described (see Table 61-1).[85,166,169-173] It is assumed that all EWS/ETS fusion proteins bind similar (if not identical) target genes to induce oncogenic transformation.[173]

Overall, most cases of Ewing sarcoma appear to harbor fusions between EWS and various ETS family members. Rarely, fusions between TLS and ETS family members may be present in Ewing sarcoma instead, as shown by the identification of TLS/ERG fusions in four patients with Ewing sarcoma and the identification of a TLS/FEV fusion in another case (see Table 61-1).[174,175] These findings highlight the similarities across the TET family and across the ETS family. Perhaps the most generic manner of describing the fusion proteins in Ewing sarcoma would be as "TET/ETS fusions."[173] Because EWS/FLI is the most common fusion identified in Ewing sarcoma, most of the experimental work has been performed using this fusion protein. Experimental findings based on EWS/FLI have only occasionally been confirmed using other Ewing sarcoma fusion proteins.

In addition to variability of fusion partners, variability also exists in the exonic structure of some of the fusion proteins (Fig. 61-4). The breakpoints found in Ewing sarcoma translocations occur in the introns of *EWSR1* and *FLI1* (and presumably the other ETS factors as well, although in most cases this has not been experimentally

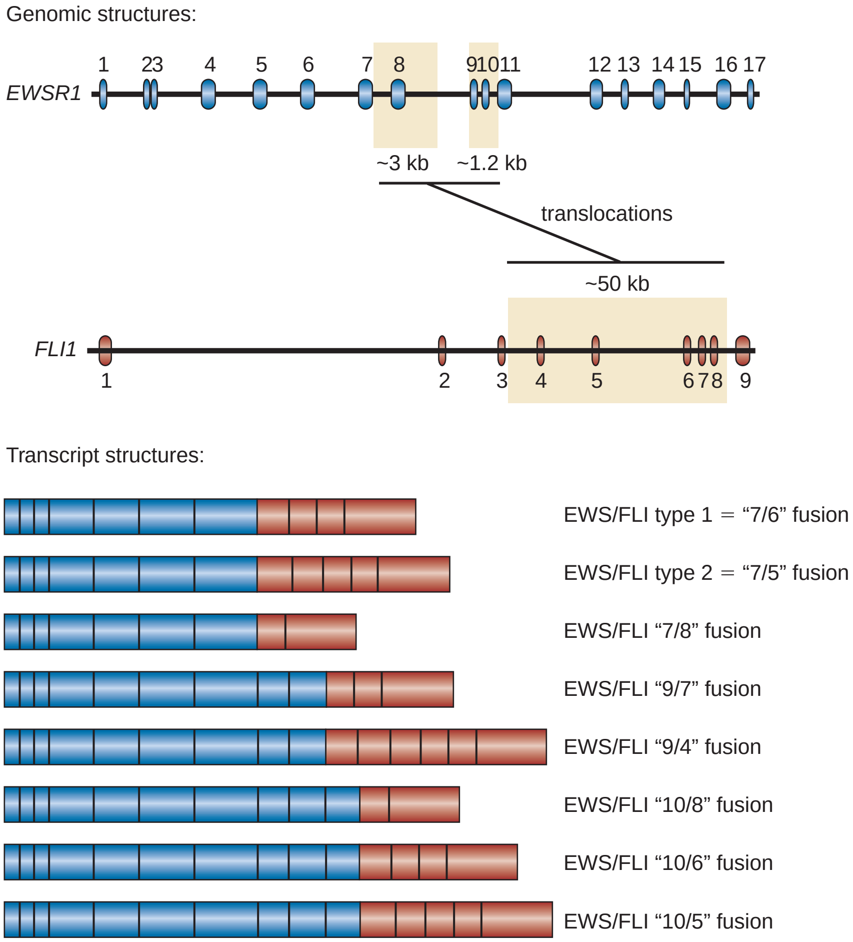

Figure 61-4 Translocation breakpoints may occur within one of two portions of a 6-kb region of the *EWSR1* gene and in a 50-kb region of the *FLI1* gene. This variety results in the observed heterogeneity of EWS/FLI fusion transcripts, as indicated.

confirmed).[85,86,176,177] The breakpoints in the *EWSR1* gene are found in one of two regions (3 kb and 1.2 kb in size) present in an approximately 6 kilobase (kb) region that includes four of the gene's 16 introns.[85,86,176] The breakpoints in *FLI1* occur over an approximately 50-kb region, which includes six of eight *FLI* introns.[85,86,176] Splicing events join adjacent exons together in the fusion transcript.[85,86,176,177] As a result of this variability in breakpoint and subsequent RNA splicing, at least 10 different EWS/FLI isoforms are generated (see Fig. 61-4).[85,86,144,176-178]

The most common Ewing sarcoma translocation fuses exon 7 of *EWSR1* to exon 6 of *FLI1*.[85,177] This "7/6" fusion is commonly referred to as a "type 1" EWS/FLI fusion and accounts for approximately 50% to 60% of EWS/FLI fusions.[177,179] A "type 2" fusion joins exon 7 of *EWSR1* to exon 5 of *FLI1* and is the second most common EWS/FLI fusion, accounting for approximately 20% to 30% of EWS/FLI fusions.[85,177,179] Laboratory studies suggested that the type 1 EWS/FLI fusion was a weaker oncoprotein than the type 2 fusion, and originally it was thought to have prognostic significance.[180,181] However, these functional differences were not reflected on changes in gene expression between type 1 and type 2 fusions, and large-scale clinical correlative data did not indicate a prognostic difference based on fusion subtype.[182-184]

Although there is general agreement regarding the designation of the type 1 and type 2 fusions, there is no generalized nomenclature for the remaining fusions, and so these are best described in terms of which exons are fused to one another. In addition to variability in the EWS/FLI breakpoint, EWS/ERG has also been reported to demonstrate variability based on fusion points, with at least four fusions reported.[166,177] Because the other fusions are so rare, there is only minimal information as to whether they also show similar levels of breakpoint heterogeneity.

Ewing Sarcoma Cell of Origin

The cell of origin of Ewing sarcoma is unknown, and the subject has generated intense debate.[185] The original description by James Ewing in 1921 suggested that this "round cell sarcoma" was of endothelial origin and hence properly referred to as a "diffuse endothelioma of bone."[1] Dr. Ewing later suggested that it may arise from perivascular lymphatic endothelium.[186] A hematologic origin was proposed in the early 1970s following an in-depth evaluation of light and electron microscopic characteristics and cytochemistry of both primary tumor and cell culture specimens.[187] In the early 1980s a fibroblastic-mesenchymal derivation was proposed based on, among other things, the patterns of collagen expression of the tumor.[188,189] In the late 1980s, however, a neural crest derivation was proposed because of the occasional identification of certain neural features, such as the presence of Homer Wright rosettes, neural processes, neurosecretory granules, and neural immunohistochemical markers.[190-195] Additionally, undifferentiated Ewing sarcoma cell lines can occasionally be induced to express markers of neural differentiation, including the expression of neuritelike elongated processes, neuron-specific enolase (NSE), cholinesterase, and neural filament triplet protein.[191,193,196-199] Interestingly, there are a few examples of neural differentiation of Ewing sarcoma occurring after therapy, which further supports this theory.[156,200-202] More recently, it was shown that introduction of EWS/FLI into murine mesenchymal stem cells could result in oncogenic transformation, suggesting that these may be the cell of origin (although the same does not hold true for human mesenchymal stem cells).[203,204] This hypothesis was further supported by microarray and cell biological studies performed on Ewing sarcoma cell lines in which EWS/FLI expression was reduced using RNA interference techniques.[205,206] In the absence of EWS/FLI expression, these cells had a gene expression pattern that was reminiscent of mesenchymal stem cells and a cellular structural organization and adhesive and migratory properties that were also consistent with a mesenchymal phenotype.[205,206] Furthermore, Ewing sarcoma cells with reduced EWS/FLI expression could be induced to differentiate into other mesenchymal cell types, such as fat and bone.[205] This is a characteristic that is shared by mesenchymal stem cells.

It is important to note, however, that the phenotype of Ewing sarcoma (at least the neural crest component) may be a *consequence* of the (11;22) translocation rather than being related to the tumor's cell of origin. Introduction of EWS/FLI into NIH3T3 murine fibroblasts induces a phenotype that is highly similar to Ewing sarcoma, including the small round blue cell morphology and features of neural differentiation.[145,146] Similarly, expression of EWS/FLI in human rhabdomyosarcoma cells, neuroblastoma cells, or even normal human fibroblasts causes those cells to express genes that are similar to the genes expressed in Ewing sarcoma.[207-209] This suggests that EWS/FLI may cause transdifferentiation of its target cells. Thus the neural crest phenotype of Ewing sarcoma may be induced by EWS/FLI.

Transcriptional profiling experiments (e.g., those using oligonucleotide or complementary DNA microarrays and, more recently, RNA sequencing) in Ewing sarcoma tumors and cell lines have allowed for a comprehensive analysis of the gene expression patterns associated with this disease. One of the earliest studies compared Ewing sarcoma tumors and cell lines with other small round cell tumors of childhood, including neuroblastoma, non-Hodgkin lymphoma, and rhabdomyosarcoma.[210] These studies demonstrated that these histologically similar tumors could be distinguished from one another using gene expression data.[210] A more recent analysis compared the expression of approximately 180 sarcoma tumor samples and again showed that tumors could be distinguished using gene expression patterns.[211] Additional studies in which the gene expression pattern of Ewing sarcoma was compared with that of a variety of normal tissues supported the neural crest derivation but also suggested some similarity to endothelial cells.[212] As discussed in the preceding section, analysis of some model systems has suggested a mesenchymal stem cell origin. A definitive understanding of the cell of origin of these tumors will require additional studies. It should be noted that as of yet no genetically engineered mouse model of Ewing sarcoma has been reported, and therefore tissue-specific oncogene expression or lineage-tracing approaches have not been used to identify the Ewing sarcoma cell of origin.

EWS/FLI Target Genes

Because most studies have suggested that EWS/FLI functions as a transcription factor, the two biggest questions in the field have been (1) what genes are dysregulated by EWS/FLI and (2) what are the roles of these gene targets in oncogenic transformation? These questions are beginning to be answered. Because the cell of origin of Ewing sarcoma is unknown, most laboratory-based studies of EWS/FLI have used heterologous cell types with varying results.[155,213-218] More recent approaches have benefited from the use of "knockdown" (reduction) of gene expression using RNA interference (RNAi).[152,154,155,219-222] The RNAi technique has allowed for the analysis of EWS/FLI in patient-derived Ewing sarcoma cell lines themselves, thus avoiding the concerns associated with using heterologous cell types.[152,154,155,219-222]

Gene expression analysis of Ewing sarcoma cells in which EWS/FLI has been knocked down has allowed a comprehensive identification of the thousands of genes that are modulated by the fusion protein.[152,155,219,221] For example, increased expression of NKX2.2 and NR0B1 are required for the oncogenic phenotype of Ewing sarcoma, although the specific mechanisms by which these transcriptional regulators facilitate the transformed phenotype remains poorly understood.[155,221,223,224] Similarly, repression of TGFBR2 (the receptor for transforming growth factor β) and lysyl oxidase (LOX) by EWS/FLI are also required for tumorigenicity of Ewing sarcoma cells.[143,158]

Gene expression studies also demonstrated that EWS/FLI represses the expression of the insulin-like growth factor binding protein 3 (IGFBP-3).[152] IGFBP-3 appears to be involved in Ewing sarcoma apoptosis, and thus decreased expression of this protein appears to prevent apoptosis.[152] These data complement a growing body of literature that supports a critical role for IGF-1 signaling in Ewing sarcoma development. For example, it was shown that Ewing sarcoma tumors and cell lines express IGF-1 and IGF receptors.[225,226] IGF-1 and its receptor appear to function in an autocrine/paracrine fashion in Ewing sarcoma, and disruption of this signaling pathway blocks various functions that contribute to tumorigenesis.[225,227-232] This occurs both in Ewing sarcoma cell lines as well as in model systems.[225-239] Indeed, disruption of this pathway has shown some efficacy as a molecularly targeted therapeutic approach for this disease (discussed later).

NPY1R was identified as an EWS/FLI target gene through microarray analysis.[155] Neuropeptide Y (NPY) is a small polypeptide neurotransmitter with diverse functions.[240,241] Engagement of NPY receptors by NPY in Ewing sarcoma cell lines is growth inhibitory, suggesting a potential therapeutic role for these receptors.[241,242] This result was surprising, insofar as Ewing sarcoma cells also express the NPY ligand.[241,242] It appears likely that Ewing sarcomas are protected from the growth-inhibitory effect of NPY/NPY1R interactions by the expression of dipeptidyl peptidase IV, which cleaves NPY into a form that is unable to bind NPY1R.[243,244] This cleaved form, $NPY_{3\text{-}36}$, functions as an angiogenic factor by binding to NPY2R receptors on endothelial cells, thus providing a likely explanation for the maintenance of this growth-inhibitory autocrine pathway in Ewing sarcoma cells.[243]

Another protein that has been shown to be upregulated by EWS/FLI is vascular endothelial growth factor (VEGF).[208,245] VEGF levels are increased in Ewing sarcoma cell lines and xenografts.[246] VEGF levels are also increased in the blood of patients with Ewing sarcoma and VEGF has been shown to be expressed in 55% of Ewing sarcoma tumor samples by immunohistochemistry.[245,247,248] In the case of Ewing sarcoma, VEGF may induce not only angiogenesis but also vasculogenesis.[249,250] Blockade of VEGF function in Ewing sarcoma model systems prevents tumor growth.[246,250-252] These preclinical studies demonstrate the potential for VEGF inhibition as a therapeutic strategy for Ewing sarcoma.

Most, but not all, studies of Ewing sarcoma have shown that these tumors typically express telomerase activity.[253-256] Interestingly, it appears that hTERT, the catalytic subunit of the telomerase holoenzyme, is upregulated by EWS/ETS proteins.[245,257,258] This upregulation appears to be caused by specific binding of the ETS portion of the fusion to the *TERT* promoter.[245,258,259] These data suggest that EWS/ETS fusions regulate telomerase activity by direct activation of the *TERT* promoter.

One key protein whose expression may be regulated by EWS/FLI is CD99 (also called MIC2).[208] In human fibroblasts engineered to express EWS/FLI, the expression of CD99 closely mimicked that of the fusion protein.[208] In the early 1990s it was found that CD99 is expressed at high levels in Ewing sarcoma cells but is uncommonly found on other tumor types.[260-262] The CD99 antigen is recognized by a variety of monoclonal antibodies, including 12E7, HBA71, and O13, and these antibodies have an important role in the diagnosis of Ewing sarcoma (discussed later).[260-269] The CD99 antigen is a membrane glycoprotein that plays a role in T-cell development and activation and migration of monocytes through endothelial junctions.[270-279] In Ewing sarcoma CD99 inhibits neural differentiation and thus contributes to oncogenic transformation.[280] Significantly, emerging data suggest that antibody-mediated engagement of CD99 may eventually be exploited as a new therapeutic approach to Ewing sarcoma.[281,282] CD99 engagement in Ewing sarcoma results in apoptosis of the tumor cells.[281,282] This effect enhances tumor cell killing by chemotherapeutic agents.[281,283] Gene expression studies of CD99-mediated apoptosis suggested a role for the cytoskeletal protein zyxin in this process, and this finding was confirmed through functional studies.[284] The identification of zyxin in this process was interesting in light of subsequent studies demonstrating that zyxin acts as a tumor suppressor in Ewing sarcoma.[285] Taken together, these studies suggest that CD99 may be an effective therapeutic target in Ewing sarcoma by modulating cytoskeletal actin function.

Cooperative Pathways in Ewing Sarcoma Oncogenesis

Multiple potentially cooperating mutations in addition to TET/ETS fusions have been identified in Ewing sarcoma. The most widely assessed are mutations in the p53 and RB pathways. The p53 pathway includes proteins such as $p14^{ARF}$ and MDM2, as well as p53 itself.[286-290] When expressed in some heterologous systems, such as primary human fibroblasts, EWS/FLI induces the expression of p53.[208] This finding suggests that there is selective pressure to inhibit the p53 pathway. This hypothesis appears to be at least partially true. Deletions in the *CDKN2A* locus (commonly called the *INK4a* locus encoding both the $p14^{ARF}$ and $p16^{INK4a}$ proteins; note that $p14^{ARF}$ is involved in the p53 pathway, whereas $p16^{INK4a}$ is involved in the RB pathway) have been identified in approximately 10% to 30% of primary Ewing sarcoma tumors and more than 50% of Ewing sarcoma cell lines.[291-293] Amplifications or overexpression of *MDM2* is occasionally seen in Ewing sarcoma.[294-297] Mutations in p53 are found in 5% to 20% of Ewing sarcomas.[293,294,297-299] Taken together, mutations in the p53 pathway may be present in nearly 70% of Ewing sarcomas, and these mutations may have prognostic significance in this disease (discussed later). Because there are likely additional components of the pathway yet to be identified or analyzed, the frequency of alterations in this pathway may be even higher.

The RB pathway regulates the cell cycle and includes proteins such as CDK4, D-type cyclins, and $p16^{INK4a}$.[300-302] Mutations have been found in RB itself, and deletions of the *INK4a* locus have been documented as well in Ewing sarcoma.[291,292,303] As was observed in the case of the p53 pathway, mutations in the RB pathway also appear to be relatively common in this disease.[291,292,303]

Whereas mutations in the p53 and RB pathways are relatively common in Ewing sarcoma, mutations in other genes or pathways have only rarely been identified. For example, mutations in BRAF (which is also a member of the RAS/MAPK pathway) have been identified in 1 of 22 cell lines examined.[304] No mutations in other components of the pathway, including RAS or receptor tyrosine kinases, have been identified, as of yet. This suggests that the RAS/MAPK pathway is only rarely activated by mutation in this disease.

Although the RAS/MAPK pathway does not appear to be frequently activated by mutation, there is some evidence for a requirement of pathway activation in Ewing sarcoma tumor development. In the NIH3T3 model system, it was shown that expression of EWS/FLI induced phosphorylation of the ERK1 and ERK2 proteins (downstream members of the MAPK pathway).[305] This effect may result from autocrine stimulation of these transformed cells by PDGF-C, which was also shown to be induced by EWS/FLI expression in the NIH3T3 model, and expressed in Ewing sarcoma cell lines and tumor specimens.[215,306] There is some controversy as to whether PDGF-C plays a role in the human disease, as PDGFR-α, which is required for PDGF-C responsiveness, is not expressed in Ewing sarcoma.[307] Although PDGF-C may not be involved in Ewing sarcoma, inhibition of the MAPK pathway does block oncogenic transformation mediated by EWS/FLI in the NIH3T3 model.[305] This finding was not replicated in Ewing sarcoma cells, thus raising the question as to whether this is an NIH3T3-specific pathway.

Many members of the Wnt signaling pathway are expressed in Ewing sarcoma, including soluble Wnt ligands, Wnt receptors (frizzled), and Wnt coreceptors (LRP5/6).[308] Additionally, microarray analysis of EWS/FLI target genes has demonstrated downregulation of the Wnt inhibitor DKK1 and upregulation of various Wnt signaling components.[155,207,221] These data suggest that Wnt signaling occurs in Ewing sarcoma. In contrast, analysis of the pathway in Ewing sarcoma cell lines in tissue culture has not demonstrated evidence of active Wnt autocrine signaling.[207,308] If the pathway is involved in Ewing sarcoma, it seems likely that it is important for processes such as migration and metastasis, rather than proliferation and transformation.[308] Current studies have not addressed this possibility.

Finally, genes involved in chromosomal stability or chromatin remodeling have also been implicated in Ewing sarcoma. For example, the STAG2 protein helps regulate chromosomal separation during mitosis and was found to be deleted in a number of human tumor types, including Ewing sarcoma.[309] It was suggested that this may be a mechanism of chromosomal instability in Ewing sarcoma and other tumors.[309] Deletion of *SMARCB1* (encoding the SMARCB1/INI1/SNF5 protein) was found in approximately 10% of Ewing sarcoma cases.[81] SMARCB1 is a member of the SWI/SNF chromosome remodeling complex whose deletion is tightly associated with atypical teratoid/rhabdoid tumor.[310] Whether SMARCB1-deleted Ewing sarcoma tumors represent a unique subset of Ewing sarcoma or instead indicate that alterations in chromatin remodeling complexes are widespread in Ewing sarcoma is currently unknown. Interestingly, a newly identified chromosomal rearrangement, t(4;22)(q31;q12), encodes an EWS/SMARCA5 fusion protein in tumors that appear consistent with Ewing sarcoma, supporting the idea that alterations in this chromatin remodeling complex may indeed be widespread in this disease.[311] Another possibility is that the EWS/SMARCA5 fusions are found in tumors that are similar, but not identical, to Ewing sarcoma.[173] Indeed, the most recent World Health Organization guidelines have named these (and other non-TET/ETS translocation-bearing tumors that have similar appearance to Ewing sarcoma; see Table 61-1) as *Ewing-like sarcomas*.[312]

Apoptotic Pathways in Ewing Sarcoma

As described previously, mutations in the p53 pathway are relatively common in Ewing sarcoma. These mutations likely confer resistance to the growth effects of TET/ETS fusions in the disease and may also protect against apoptosis.[208,313,314] Whereas p53 is an important mediator of apoptosis, other signaling pathways are involved as well. These other pathways have been evaluated in Ewing sarcoma in a number of studies.

Both Fas and the Fas ligand (FasL) are expressed in the majority of Ewing sarcomas.[315-317] The status of the FasL in Ewing sarcoma is somewhat controversial; one study reported soluble FasL in Ewing sarcoma–conditioned media,[317] whereas another study reported that the FasL is only found intracellularly and thus is not accessible to cell surface receptor.[315] In terms of the receptor, Fas at the cell surface can be functional, but Ewing sarcoma cells can be divided into Fas-sensitive, Fas-inducible, and Fas-resistant groups.[315] Fas-sensitive lines are killed by coincubation with a FasL-expressing effector cell.[315] Fas-inducible lines are killed by this effector cell line only after pretreatment with interferon-γ (IFN-γ) or cycloheximide (or both).[315] The Fas-resistant lines were resistant regardless of pretreatment.[315] The differences between sensitive and resistant cells are not completely known but may involve differences in Fas expression or expression of proapoptotic or antiapoptotic mediators, such as BAD and BAR.[315,318] Strategies to improve Fas-mediated killing of Ewing sarcoma cells have been investigated, such as allowing for accumulation of more FasL through the use of metalloproteinase inhibitors[319] and upregulation of Fas by administration of interleukin-12.[320,321]

In addition to Fas/FasL, evaluations of tumor necrosis factor–related apoptosis-inducing ligand and tumor necrosis factor α as inducers of Ewing sarcoma apoptosis have also been conducted, in vitro and in vivo, alone and in combination with other agents.[322-333] Taken together, these data support a potential use of proapoptotic ligands in the treatment of Ewing sarcoma. However, the variability of the effects seen demonstrate the need for an ongoing mechanistic evaluation of these pathways in this disease.

Biological Features Summary

The identification of t(11;22)(q24;q12) and subsequent cloning of the EWS/FLI fusion protein represented a major advance in the understanding of the pathogenesis of Ewing sarcoma. EWS/FLI appears to function primarily as an aberrant transcription factor to dysregulate gene targets involved in the development of this disease. Multiple gene targets and cooperating molecular pathways have been identified. These represent a wide array of functions, including growth factor signaling, survival and apoptosis pathways, angiogenesis, cellular immortalization, and cellular differentiation. Despite these myriad molecular functions, a unified mechanistic understanding of Ewing sarcoma development has not yet been reached. Similarly, the cell of origin of the disease has not yet been clearly identified. Nonetheless, there is great hope that a detailed understanding of the molecular mechanisms involved in Ewing sarcoma development will lead to new diagnostic, prognostic, and therapeutic approaches for this disease.

CLINICAL PRESENTATION AND DIAGNOSIS

Clinical Presentation

The most common presenting symptoms of Ewing sarcoma are pain, a palpable mass, or both. In one series 89% of patients with Ewing sarcoma reported pain at the time of initial presentation.[334] Pain does not necessarily occur at night; this pattern was reported in only 19% of patients in one series.[334] Patients may report that their pain began at the same time as a minor musculoskeletal injury. This presentation, reported in approximately 25% of patients, may delay the diagnosis.[334] Unlike patients with osteosarcoma, patients with Ewing sarcoma may report constitutional symptoms such as fever and weight loss. Approximately 15% to 20% of patients have fever at presentation.[335-337] Other symptoms depend on the site of disease. For example, 40% to 94% of patients with paraspinal tumors have presenting symptoms of spinal cord compression.[338-341] Patients with large pelvic tumors may complain of an alteration in voiding. Extensive bone marrow metastatic disease may cause symptoms related to anemia, thrombocytopenia, or neutropenia. Patients may have symptoms for many weeks or months before seeing a physician for evaluation, with most studies reporting an average time from symptom onset to diagnosis of 3 to 5 months.[342-344]

Ewing sarcoma can arise from any bone but has a predilection for pelvic bones and long bones of the leg. Approximately 45% of Ewing sarcomas develop in the axial skeleton. More than half of these axial tumors arise from pelvic bones, and a quarter of axial tumors arise from a rib.[4,5] Up to 30% of Ewing sarcomas arise from long bones in the leg, and up to 15% of tumors develop in long bones in the arm.[4,5] Tumors of the hands, feet, and head develop only rarely, accounting for 10% or fewer of all tumors.[4,5] The distribution of primary tumor site does not vary among racial groups.[10] Soft tissue tumors may arise in any location, although axial sites predominate.[345,346]

Laboratory studies in patients with newly diagnosed Ewing sarcoma may reveal nonspecific abnormalities. More than a third of patients have an elevated erythrocyte sedimentation rate (ESR) at the time of diagnosis.[337,347] Similarly, serum lactate dehydrogenase (LDH) levels are elevated in approximately one third of patients.[336,347-349] Laboratory manifestations of tumor lysis syndrome are uncommon with these tumors. Unlike osteosarcoma, alkaline phosphatase is not typically elevated in patients with Ewing sarcoma of the bone. Patients with advanced bone marrow metastatic disease may have anemia, thrombocytopenia, and neutropenia detected on a complete blood count. In one large series 12% of patients had anemia even in the absence of metastatic disease.[336]

Box 61-1 summarizes the differential diagnosis of Ewing sarcoma. In most cases of Ewing sarcoma of the bone, the main alternative diagnosis is osteosarcoma. Table 61-2 displays features that may help differentiate Ewing sarcoma of the bone from osteosarcoma. Compared with osteosarcoma, Ewing sarcoma is more likely to occur in the axial skeleton. Those Ewing tumors that arise in long bones have a greater tendency to occur in the diaphysis, compared with the tendency of osteosarcoma to arise in the metaphysis of long bones.[350] Patients with Ewing sarcoma are more likely to report constitutional symptoms than are patients with osteosarcoma. Other malignant tumors in the differential diagnosis of Ewing sarcoma of the bone include primary bone lymphoma, giant cell tumor of the bone, and bone metastasis of an extraosseous malignancy. The differential diagnosis of Ewing sarcoma arising from the soft tissues is more broad because the site of origin for these tumors is not restricted to the bone. The site of origin may help narrow the differential diagnosis. Paraspinal tumors may be confused with neuroblastoma, particularly in younger patients. Pelvic tumors may suggest rhabdomyosarcoma or malignant germ cell tumor. Lymphoma and other soft tissue sarcomas can arise at any site and should be included in the differential diagnosis.

Reports from several cooperative group studies have defined the metastatic behavior of Ewing sarcoma. Approximately 25% of patients exhibit distant metastases at presentation.[351,352] Rates of metastatic disease do not appear to differ between patients with skeletal tumors and those with soft tissue primary tumors.[346] Patients with pelvic primary tumors have an increased incidence of metastatic disease at initial diagnosis.[353] The lung is the most common metastatic site, with pulmonary dissemination reported in 50% to 60% of patients with metastatic disease.[354,355] Patients with isolated pulmonary metastasis represent between 26% and 36% of cases of metastatic disease.[354,356] Patients usually have multiple lung nodules identified in both lungs.[351]

The bone is the next most common metastatic site at presentation. One group reported cortical bone metastases in 43% of patients with metastatic disease.[355] A large

TABLE 61-2 Clinical Differentiation of Ewing Sarcoma of Bone from Osteosarcoma

	Ewing Sarcoma	Osteosarcoma
Age distribution	Peak in adolescence Occurs in young children Very rare in adults >40 years	Peak in adolescence Very rare in children <5 years Occurs in older adults
Racial distribution	Rare in patients of African or East Asian ancestry	No racial predilection
Predisposing factors	Not associated with radiation No known familial predisposition	Radiation exposure Li-Fraumeni syndrome History of retinoblastoma
Constitutional symptoms	Yes	No
Involved bones	Both flat and long bones	Long bones more common
Location in long bones	Diaphyseal more common	Epiphyseal/metaphyseal more common
Type of periosteal reaction	Laminated/layered "Onion-skinning"	Spiculated "sunburst"
Laboratory findings	Normal alkaline phosphatase Abnormal CBC if marrow disease	Elevated alkaline phosphatase Normal CBC
Histologic findings	Small round blue cells No malignant osteoid	Malignant spindle cells Malignant osteoid

CBC, Complete blood count.

cooperative group reported that the bone marrow is involved in approximately 19% of metastatic patients at initial diagnosis.[355] A smaller series noted bone marrow involvement in 52% of patients with metastatic disease.[357] This group performed up to 10 bone marrow aspirates on patients at initial presentation, suggesting that routine sampling may underestimate the incidence of bone marrow involvement. Brain metastasis at initial diagnosis appears to be extremely uncommon. In two series of patients with brain metastasis from Ewing sarcoma, all cases were reported at the time of disease recurrence and not at initial presentation.[358,359]

Fewer than 10% of patients have lymph node involvement at initial diagnosis.[360] The incidence of node involvement is higher in patients with soft tissue rather than bone primary tumors.[355,360,361] In one population-based study, the incidence of regional node involvement among patients with soft tissue tumors was 12.4% compared with 3.2% in patients with bone primary tumors.[360] The incidence of regional node involvement is also higher among patients with distant metastatic disease.[360]

This metastatic pattern helps determine the appropriate staging evaluation for patients with Ewing sarcoma (Box 61-2). In addition to computed tomography (CT) or magnetic resonance imaging (MRI) scans of the primary tumor, all newly diagnosed patients should be evaluated with a chest CT scan. Assessment for bone metastasis has conventionally been with radiolabeled-technetium bone scan. More recent data indicate that positron emission tomography (PET) scans are superior for this indication (discussed later), prompting wider adoption of PET imaging at initial diagnosis.[362] At least bilateral bone marrow aspirates and biopsies should routinely be performed in newly diagnosed patients, with biopsy more sensitive for detection of marrow involvement compared with aspirate.[363] Attention to regional nodes on imaging studies is particularly warranted in patients with soft tissue primary tumors. These evaluations will indicate whether a patient has metastatic or nonmetastatic Ewing sarcoma at initial diagnosis. This distinction serves as the main staging classification in practice for these patients. Although a staging classification for musculoskeletal tumors has been devised by Enneking, this system is not routinely used in the clinical care of patients with Ewing sarcoma.[364]

Imaging Features

Most patients with Ewing sarcoma of the bone are initially evaluated with a plain radiograph. Two representative radiographs are shown in Figure 61-5. These tumors typically appear as poorly circumscribed lesions arising from the bone, but with an associated soft tissue mass.[350] Both lytic and sclerotic areas may be seen within the bony component of the tumor. Given the aggressive nature of these tumors, periosteal reaction is commonly observed. A layered or laminated periosteal reaction is most typical, often giving an onion-skin appearance (see Fig. 61-5, *A*).[350,365] A spiculated "sunburst" periosteal reaction is more commonly associated with osteosarcoma but may be occasionally observed in Ewing sarcoma (see Fig. 61-5, *B*).[350] Codman triangle, a triangular area forming under the periosteum in the setting of a rapidly growing bone lesion, may also be seen in some cases. Cortical thickening is present in approximately 20% of tumors.[350] Pathologic fractures occur in 15% of patients with Ewing sarcoma of bone.[337,350,366]

CT scans and MRI scans are used to better define the extent of local tumor in patients with both osseous and

extraosseous tumors. CT scans most commonly demonstrate a heterogeneous mass with heterogeneous contrast enhancement.[367-371] The soft tissue component generally has lower attenuation than muscle on non-enhanced CT scans.[367,369,372] MRI scans typically reveal a mass that is heterogeneous with respect to both signal intensity and gadolinium contrast enhancement.[370,371,373] Typically T1- and T2-weighted MRI scans demonstrate areas of increased signal intensity of the soft tissue component compared with skeletal muscle.[367,370,371] Although both CT and MRI are able to delineate the soft tissue component of the tumor, MRI may be better able to determine the extent of bone marrow extension and the degree of growth plate involvement.[374]

Emerging evidence suggests that fluorodeoxyglucose PET (FDG-PET) may play an increasing role in the management of patients with Ewing sarcoma. In one series all 32 patients with Ewing sarcoma evaluated by FDG-PET imaging before initiation of chemotherapy had FDG-avid tumors.[375] Figure 61-6 demonstrates an FDG-PET scan of a patient with widely metastatic Ewing sarcoma at initial presentation. A group of studies has evaluated the role of FDG-PET imaging in screening for metastatic disease and for disease recurrence. Several groups have demonstrated that FDG-PET imaging has superior sensitivity and specificity compared with conventional bone scans for detecting bone metastases in patients with Ewing sarcoma.[376-378] In contrast, FDG-PET appears to be inferior to spiral CT scans in screening for pulmonary metastases in these patients.[379] In screening patients with Ewing sarcoma for overall disease recurrence at any site, FDG-PET imaging may have lower sensitivity but higher specificity compared with conventional imaging.[380] Finally, one group has reported that a decrease in FDG-avidity in response to neoadjuvant chemotherapy correlates with improved progression-free survival.[375]

Pathologic Diagnosis

Once imaging studies have localized the tumor, diagnostic tissue must be obtained. The current pathologic diagnosis of Ewing sarcoma depends on tumor morphology, immunohistochemistry findings, and demonstration of a Ewing sarcoma–specific translocation (by standard cytogenetics, fluorescence in situ hybridization [FISH], or reverse transcriptase polymerase chain reaction assays [RT-PCR]).[381] In planning for biopsy, the physician must ensure that adequate tissue will be available to perform each of these tests. For example, one series reported successful cytogenetic analysis in only 59% of fine needle aspirations performed for Ewing sarcoma.[382] The biopsy should be planned with an eye toward ultimate local control of the tumor. If surgical resection is ultimately planned, the biopsy tract should be included in the resected specimen.[383]

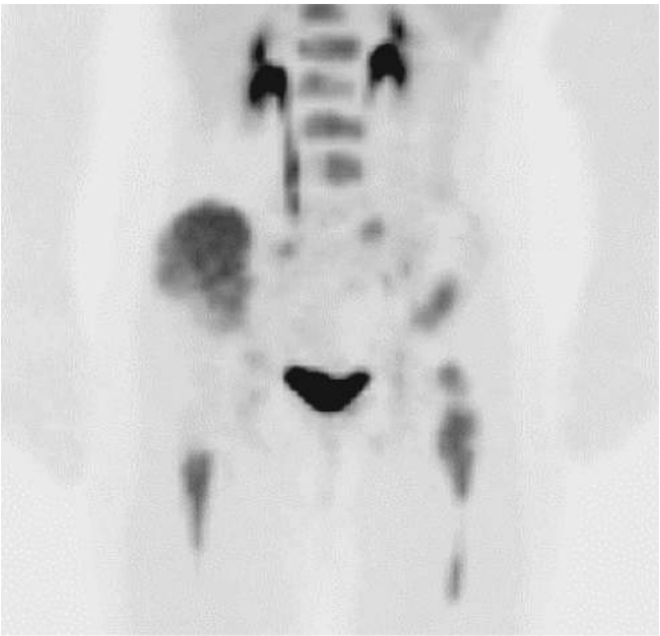

Figure 61-6 Whole-body fluorodeoxyglucose positron emission tomography (FDG-PET) scan of a patient with widely metastatic Ewing sarcoma at initial diagnosis. FDG uptake is evident in bones, soft tissue, and bone marrow.

Ewing sarcoma and PNET form a morphologic continuum ranging from tumors with no apparent neural differentiation to tumors with evidence of early neural differentiation. Of note, the histologic classification of these tumors does not imply site of origin because tumors with either histology may arise in the bone or soft tissue. Ewing sarcoma appears as relatively monomorphic small round blue-staining cells with scant cytoplasm (Fig. 61-7).[384,385] The nuclei tend to be round without prominent nucleoli.[384,385] These cells demonstrate positive periodic acid–Schiff staining owing to cytoplasmic glycogen.[381,385] Electron microscopy may reveal these glycogen stores.[381,385] The tumor cells grow in sheets without additional structure.[384-386] A large cell or atypical Ewing sarcoma subset has been described with large irregular nuclei and more conspicuous nucleoli.[384-386] As many as 30% of tumors with Ewing sarcoma histology arise in soft tissues rather than bone.[384,386] PNETs typically display primitive Homer Wright pseudorosette formation.[384,386] Electron microscopy may reveal additional features suggestive of neural differentiation, such as neurosecretory granules.[381,385,387] Tumors without pseudorosette formation may also be classified as PNETs if they express two or more neural markers (discussed later).[386] Approximately 50% of tumors with PNET histology arise in bone.[384,386] Despite these morphologic differences, Ewing sarcoma and PNET are now viewed as the same biological entity.

Immunohistochemistry plays a key role in differentiating Ewing sarcoma and PNET from other small round cell tumors of children and young adults. The most useful antigen in the diagnosis of Ewing sarcoma appears to be CD99. This protein product of the *MIC2* gene is expressed in a limited number of normal tissues, including strong staining of ependymal cells, pancreatic islet cells, anterior pituitary gland, testicular Sertoli cells, ovarian granulosa cells, and maturing T lymphocytes.[261,388] Less intense staining has been noted in scattered endothelial cells.[261] Ewing sarcoma and PNET both display prominent CD99 immunostaining in a membranous pattern (see Fig. 61-7). Multiple series have found strong CD99 immunostaining in more than 90% of cases of Ewing sarcoma and PNET.[261-263,268,269,388-391] Staining for neural markers, such as synaptophysin, S-100, NSE, and neurofilament, is variable and helps to characterize tumors as Ewing sarcoma or PNET.[381,384-386] These tumors also commonly stain with vimentin, whereas desmin staining is distinctly uncommon.[384,386,392] Approximately 30% of Ewing sarcomas and PNETs demonstrate diffuse c-kit (CD117) staining.[393-395]

Several tumors also express CD99 and may confuse the diagnosis. Strong CD99 immunostaining has been observed in ependymoma, glioblastoma, and pancreatic islet cell tumors.[261,388] These tumors are not typically within the clinical differential diagnosis of Ewing sarcoma or PNET. In contrast, lymphoblastic lymphoma (particularly T-cell), neuroblastoma, alveolar rhabdomyosarcoma, synovial sarcoma, and desmoplastic small round cell tumor may demonstrate variable levels of CD99 staining and are frequently considered in the differential diagnosis of these tumors.[261,392,396-400] Whereas both Ewing sarcoma and lymphoblastic lymphoma may demonstrate strong CD99 staining, Ewing sarcoma and PNET should be negative for lymphocyte markers, particularly leukocyte common antigen and terminal deoxynucleotidyl transferase.[386,392,398] Ewing sarcoma and PNET are also

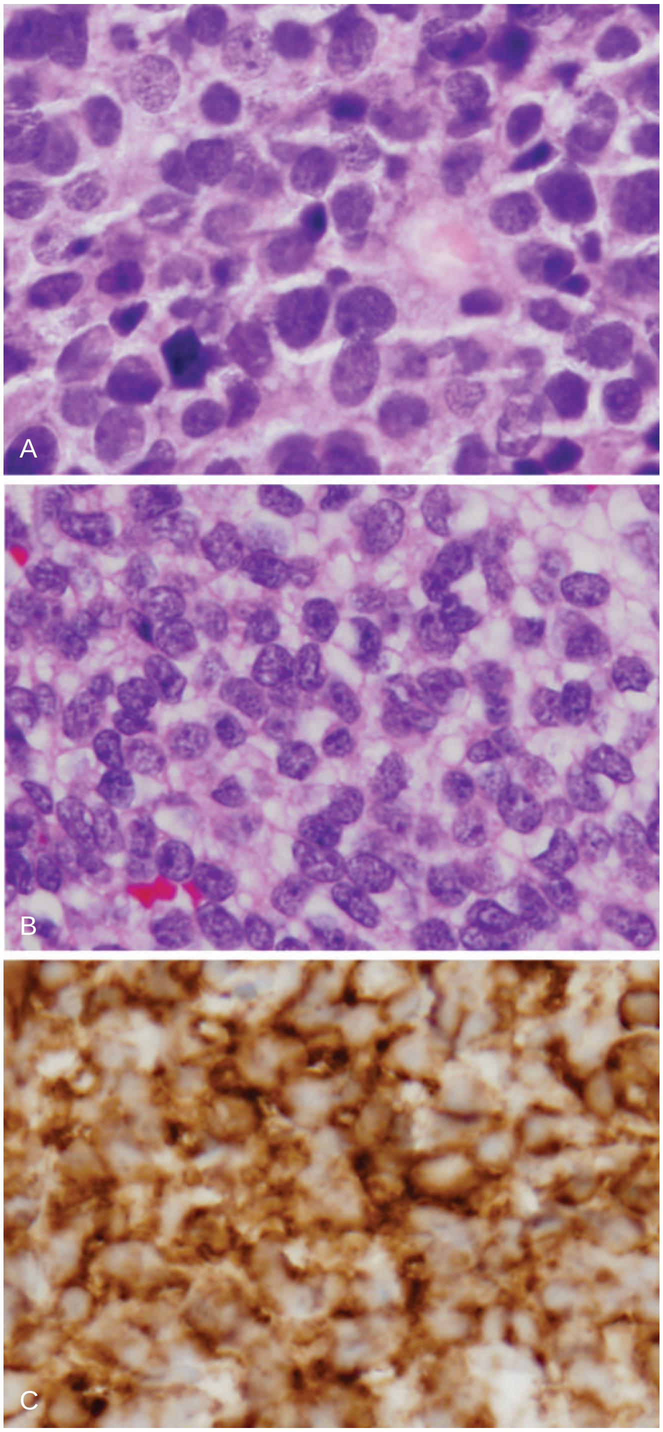

Figure 61-7 **A**, Characteristic morphology of Ewing sarcoma with monomorphic small round blue cells without pseudorosette formation. **B**, Morphologic features of a primitive neuroectodermal tumor (PNET), including a pseudorosette formation in the center of the panel. **C**, The characteristic strong membranous CD99 immunohistochemical staining of Ewing sarcoma. *(Courtesy Dr. Antonio Perez-Atayde, Department of Pathology, Children's Hospital, Boston, Mass.)*

more likely to demonstrate strong vimentin staining compared with lymphoblastic lymphoma.[392] The immunohistochemical differentiation of Ewing sarcoma and PNET from neuroblastoma is typically more straight-forward largely because CD99 staining in neuroblastoma, if present, is weak and patchy.[261,397] Neuroblastomas commonly demonstrate strong staining with NSE, whereas Ewing sarcoma and PNET occasionally will show weak to moderate NSE staining.[263,397] Poorly differentiated synovial sarcoma and desmoplastic small round cell tumor may both also demonstrate CD99 staining and morphologically be difficult to differentiate from Ewing sarcoma and PNET.[396,399,400] In both cases strong membranous staining is more consistent with Ewing sarcoma and PNET. In contrast, weak staining for CD99 and strong staining for cytokeratin and epithelial membrane antigen suggest synovial sarcoma.[396,399] Desmoplastic small round cell tumors reliably demonstrate nuclear staining for WT1, whereas Ewing sarcoma and PNET typically do not stain with WT1.[400] Nuclear staining for FLI1 may also help differentiate these tumors from other pediatric CD99 small round cell tumors. Most cases of Ewing sarcoma and PNET demonstrate nuclear FLI1 staining, whereas synovial sarcoma, neuroblastoma, and rhabdomyosarcoma only rarely show positive nuclear FLI1 staining.[384,401,402] Significantly, however, a high proportion of lymphoblastic lymphomas also exhibit nuclear FLI1 staining.[401] Finally, a number of small round cell tumors of bone harboring novel translocations have been described (see Table 61-1). These have recently been classified as Ewinglike sarcomas.[312] As an example, a *BCOR/CCNB3*-containing tumor has recently been described. This entity has a gene expression profile that is distinct from that of Ewing sarcoma, demonstrates membranous CD99 positivity in only a minority of cases, and can be identified by intense immunohistochemical staining for CCNB3.[403]

The combination of characteristic morphology and immunohistochemistry typically allows an experienced pathologist to render the diagnosis of Ewing sarcoma or PNET. The identification of recurrent chromosomal translocations and their associated oncoproteins in these tumors has allowed for the incorporation of molecular testing into their diagnosis. These methods play a role as confirmatory tests in the setting of typical morphology and immunohistochemistry. In more unusual cases these molecular tests may serve as the key feature on which the diagnosis is based. Although these molecular approaches have been very effective, it is worth recognizing their strengths and weaknesses when interpreting diagnostic studies.

Karyotypic analysis is one approach to confirming the diagnosis of Ewing sarcoma. The presence of one of the characteristic translocations can be considered strong supportive evidence for the diagnosis.[66-68,404,405] It is important to recognize that false-negative results may occur from a number of sources, including overgrowth of nonmalignant elements during culture, complex translocations in which the characteristic Ewing-associated rearrangement is partially masked by the presence of an additional fusion partner,[68,406-408] and cryptic rearrangements in which the translocation cannot be identified using typical techniques.[407,409] FISH can be very helpful as a complementary technique to demonstrate that the *EWSR1* locus is “split,” which suggests a translocation event.[407,410-414] FISH for the *FLI1* and/or *ERG* loci that demonstrates a split signal from either of these genes or fusion between *EWSR1* and *FLI1* or *ERG* signals provides additional strong evidence for involvement of these genes in the rearrangement.[407,410-414] A false-negative FISH result may occur when the fusion involves a rarer translocation partner, such as TLS (in lieu of EWS) or ETV1, ETV4, or FEV (in lieu of FLI or ERG).[169-172,175] These rare translocations are not typically included in the molecular diagnostic evaluation of these tumors.

A positive *EWSR1* “split” FISH assay is not specific for the diagnosis of Ewing sarcoma because of the presence of *EWSR1* rearrangements in tumor types other than Ewing sarcoma (see Table 61-1). For example, clear cell sarcoma (also called malignant melanoma of the soft parts) usually harbors a t(12;22)(q13;q12) rearrangement.[415] This translocation fuses EWS to the ATF1 protein to form the EWS/ATF1 protein.[415] Similarly, desmoplastic small round cell tumor harbors a t(11;22)(p13;q12) rearrangement.[416] This fuses the EWS protein to the Wilms tumor suppressor WT1 to form the EWS/WT1 protein.[416] EWS or TAF15 can join the NR4A3 orphan nuclear receptor to form EWS/NR4A3 and TAF15/NR4A3 fusion proteins in extraskeletal myxoid chondrosarcoma.[107,417-420] EWS is occasionally fused to DDIT3 (also called CHOP) to form EWS/DDIT3 in t(12;22)(q13;q12) positive myxoid liposarcoma.[421] An EWS/ZNF278 fusion was identified in a small round cell sarcoma as a result of a t(1;22)(p36;q12) rearrangement.[422] In some cases there may be diagnostic confusion between some of these tumor types and Ewing sarcoma, and thus the presence of a rearranged *EWSR1* locus may not be adequate for diagnostic purposes. In rare instances tumors may show biphenotypic differentiation with both neural and myogenic patterns. At least some of these express EWS rearrangements (EWS/FLI or EWS/ERG fusions) as well as the classic PAX3/FKHR fusion protein associated with alveolar rhabdomyosarcoma.[423-425]

The use of RT-PCR may provide greater specificity in the diagnosis of Ewing sarcoma. RT-PCR is a useful method for detection of EWS/ETS fusions.[414,426-428] As with any PCR-based method, false-positive results may occur from contamination. False-negative results may occur because of degradation of the RNA, alternate fusion partners, or because an RT-PCR primer pair may be designed to detect some EWS/FLI transcripts but not others.[426-428] False-negative results may also occur when biopsies do not capture viable tissue or primarily include nonmalignant elements. Despite their shortcomings, molecular techniques have become an important addition to the diagnostic approach for Ewing sarcoma.

PROGNOSTIC FACTORS

A number of clinical and molecular features have been identified as prognostic variables in patients with Ewing sarcoma. The presence of metastatic disease at initial diagnosis is widely regarded as the most important adverse clinical prognostic feature. In the largest analysis of prognostic features in this disease, patients with metastatic disease at presentation had a 5-year relapse-free survival rate of 21% compared with 55% for nonmetastatic patients.[353] Patients in this analysis received therapy according to several sequential treatment protocols. Patients with metastatic disease treated in the North American study INT-0091 had a similar 5-year event-free survival rate of 22% regardless of their chemotherapy regimen.[352] Patients with isolated lung metastases have a better outcome than patients with dissemination to other sites or with dissemination to lungs plus other sites.[351,353,356,429] Within this group of patients, patients with unilateral lung metastases may fare better than patients with bilateral lung metastases.[351] Dissemination to regional lymph node is also an adverse prognostic factor, even among patients with otherwise localized disease.[360]

Tumor size has long been recognized as a predictor of outcome in patients with Ewing sarcoma. Patients with larger tumors are at increased risk for having metastatic disease at initial diagnosis. For example, a pooled analysis of German patients treated in the European Intergroup Cooperative Ewing's Sarcoma Study (EICESS) and Cooperative Ewing's Sarcoma Study (CESS) indicated that tumor volume greater than 100 mL was an independent predictor of metastatic disease at initial diagnosis.[430] The effect of tumor size on outcome does not depend entirely on this increased risk of metastatic disease, however. Tumor size appears to be prognostic even among patients with initially nonmetastatic tumors. The CESS-81 study demonstrated that tumor volume greater than 100 mL was a significant adverse prognostic factor for patients treated with either surgery or radiation.[431] The follow-up CESS-86 study found that tumor volume greater than 200 mL was a major adverse prognostic feature for patients with localized Ewing sarcoma.[432,433] The North American INT-0091 study reported that nonmetastatic patients with tumors greater than 8 cm in maximal dimension had an inferior outcome compared with patients with smaller tumors.[352] The French EW88 study reported that tumor size, using either tumor volume or longest dimension, was prognostic only among patients who received radiotherapy alone as the mode of local control.[347] Although some smaller studies have not observed this effect of tumor size on outcome,[434] most investigators consider tumor size prognostic. Indeed, a large pooled analyses of prognostic factors in Ewing sarcoma identified large tumor volume as an independent predictor of poor outcome.[353]

Tumor site is also widely considered a prognostic factor in Ewing sarcoma, with axial tumors carrying a worse prognosis. The Intergroup Ewing Sarcoma Study 1 (IESS-1) established pelvic site as an unfavorable prognostic feature.[435] Several other cooperative group studies have confirmed this finding and indicated that patients with axial tumors generally have a worse outcome compared with patients with nonaxial tumors.[343,352,436,437] In many of these studies, patients with pelvic primary tumors have been shown to have a particularly poor outcome compared with patients with other axial locations.[343,352,436] However, the inferior outcomes in patients with pelvic tumors may be confounded by a higher incidence of both large tumor size and metastatic disease.[353,430] For example, in the CESS-86 trial, axial tumor location was a significant adverse prognostic feature on univariate analysis.[433] After controlling for tumor size and chemotherapy response, however, the prognostic impact of axial site became insignificant. Several groups evaluated only patients with nonmetastatic tumors and found that patients with pelvic tumors still had an inferior outcome compared with patients with nonpelvic tumors.[352,435,436] Two other groups used multivariate methods to evaluate the prognostic impact of axial tumor location in nonmetastatic patients.[336,353] Both groups reported that axial tumors have an inferior outcome compared with extremity tumors, even after controlling for potential confounders. Neither analysis controlled for tumor size, however. Therefore whether axial tumor location portends poor outcome independent of large tumor size remains unclear.

The prognostic impact of soft tissue rather than bone primary tumor origin remains unclear. In one population-based study, soft tissue origin was independently associated with improved outcomes compared with bone origin.[346] In contrast, a cooperative group clinical trial that included both patients with soft tissue and bone tumors showed equivalent outcomes.[438] As more trials include patients with soft tissue tumors, the prognostic impact of tumor origin will become clearer.

A number of groups have specifically evaluated histologic response to neoadjuvant chemotherapy as a predictor of outcome. Patients with a favorable chemotherapy response (typically 90% to 100% tumor necrosis depending on the grading scale used) at the time of surgery have been found to have a decreased risk of disease recurrence compared with patients who exhibited less necrosis.[255,347,431,433,439-442] For patients with nonmetastatic tumors of the extremity, chemotherapy response is prognostic independent of age and tumor size.[440] Despite these results, grading of chemotherapy response in Ewing sarcoma has not yet become routine practice, perhaps at least in part because this variable is not evaluable in those patients who receive definitive radiotherapy as their mode of local control. An alternative to histologic grading is radiographic grading of chemotherapy response. Two groups have reported that favorable radiographic response to chemotherapy is a predictor of favorable outcome.[433,437,439] Evaluation of radiographic response may also not be possible in all patients, particularly in patients with tumors confined to bone without an associated soft tissue mass.

Age at initial diagnosis has been increasingly recognized as an important prognostic feature in Ewing sarcoma. Several studies have indicated that younger patients have an improved outcome compared with older patients.[336,348,352,353,434,435] Older patients have an increased risk of presenting with large tumors, but interestingly they do not have a higher incidence of metastatic disease at initial diagnosis.[430] Even controlling for these potential confounders, age has been identified as an independent predictor of outcome in a number of studies.[336,348,436]

Most studies have used a single cut-point in the 12- to 15-year age range. One study divided patients into three groups (younger than 10 years, 10 to 17 years, and 18 years or older) and found that nonmetastatic patients 18 years of age or older at initial diagnosis had a particularly poor outcome (44% 5-year event-free survival rate).[352] A number of studies have focused on outcomes in older adolescents and adults with Ewing sarcoma. These studies have typically identified the same adverse prognostic features (metastatic disease, large size, axial location, and poor chemotherapy response) in older patients that have been identified in larger studies in patients at a wide range of ages.[443-446] The mechanism underlying these differences in outcome with age remains unclear. Possible explanations include biological differences in tumor and host as well as health care delivery differences in compliance and dose intensity. For example, at least two reports have noted higher rates of soft tissue tumors in adults older than 40 years of age at initial diagnosis, which suggests biological differences in this disease when it arises in older patients. Another series noted lower treatment intensity and inferior outcomes in older patients,[447,448] whereas another series reported similar treatment intensity and outcomes in older patients.[448,449] These results highlight the importance of optimizing treatment intensity to maximize outcomes in adults with this disease.

Serum LDH at initial diagnosis also appears to be prognostic. Several early studies reported that patients with elevated serum LDH levels at diagnosis had an increased risk of disease recurrence.[450-452] More recent studies have confirmed this finding and have found that the negative prognostic impact of an elevated LDH remains even after controlling for other possible confounding variables.[336,348,453] A meta-analysis evaluating a range of tumor markers in Ewing sarcoma also concluded that elevated LDH at diagnosis is associated with inferior outcomes.[454] Presumably, elevated LDH levels indicate greater tumor cell turnover and therefore more aggressive clinical behavior.

A variety of other clinical and demographic features at diagnosis have been variably reported to be prognostic in Ewing sarcoma. Two groups have reported that female sex is an independent predictor of favorable outcome.[336,348] Other groups have not corroborated this finding.[352,353,432] Other studies have demonstrated superior outcomes among the U.S. white, non-Hispanic population compared with members of other racial and ethnic groups.[12,455,456] A greater degree of neural differentiation has been reported as an unfavorable marker by some groups but not by others.* Fever, anemia, leukocytosis, elevated erythrocyte sedimentation rate, and hypoalbuminemia at initial diagnosis have also been suggested as unfavorable prognostic features, but their prognostic value has not yet been validated.[336,347,453,462]

The nature of the Ewing sarcoma–specific translocation does not appear to provide prognostic information. One group has demonstrated that patients with any type of EWS/FLI translocation have similar outcomes to patients with any type of EWS/ERG translocation.[463] Previous studies suggested that patients with a type 1 EWS/FLI translocation had better outcomes compared with other types of EWS/FLI or EWS/ERG translocations.[179] However, two large cooperative group trials both demonstrated that translocation subtype does not affect survival in the setting of modern therapy.[183,184]

Several studies have measured EWS/FLI fusion transcripts in the peripheral blood or bone marrow to predict outcome. These studies use RT-PCR techniques to identify occult metastatic disease, with 25% of clinically nonmetastatic patients noted to have detectable EWS/FLI fusion transcripts in blood or bone marrow in one early study.[464] The results of studies correlating these findings to clinical outcome have been mixed. In one report patients with clinically localized disease but positive peripheral blood EWS/FLI RT-PCR at diagnosis had a higher risk of relapse compared with patients with negative peripheral blood EWS/FLI RT-PCR.[465] A second study evaluating bone marrow EWS/FLI RT-PCR at diagnosis was not able to confirm this finding.[466] Patients in this study had follow-up EWS/FLI RT-PCR performed on blood or bone marrow (or both). Patients with positive blood or bone marrow EWS/FLI RT-PCR at their last evaluation had a significantly increased risk of clinical disease recurrence.[466] The utility of this methodology for predicting outcome in patients with Ewing sarcoma will require further prospective evaluation.

Chromosomal changes beyond the characteristic TET/ETS translocations may also provide prognostic information. Although it is the most common additional karyotypic abnormality in Ewing sarcoma, at least three groups have reported that trisomy 8 does not appear to influence outcome.[467-469] A small series of 21 patients reported that all three patients with gain of chromosome 1q died as a result of disease.[470] Another study of 88 patients with complete cytogenetic data did not observe an association between 1q gain and poor outcome, although only 12 patients had 1q gain.[469] A larger study of 124 patients with Ewing sarcoma included 26 patients with gain of chromosome 1q and found that patients with gain of chromosome 1q have a worse outcome.[467] One study reported that more global karyotypic anomalies may also be prognostic, including complex karyotypes (more than five chromosomal anomalies) or hyperdiploidy (more than 50 chromosomes).[469]

Aberrations in p53 and p16 have also been correlated with outcome in patients with Ewing sarcoma. The 10% to 15% of patients with mutations in the *TP53* gene (encoding the p53 protein) have consistently been shown to have a significantly worse outcome compared with patients who have wild-type *TP53*, even after controlling for other prognostic factors.[293,471] Additional work has suggested that mutations or deletions of the *CDKN2A/INK4A* gene may also confer a poor outcome in these patients.[292,293,472] For example, aberrant *TP53* or *CDKN2A/INK4A* gene status in one study was shown to be an independent negative prognostic feature.[293] However, another study focused exclusively on *CDKN2A/INK4A* deletion failed to show an association with prognosis.[473] A formal meta-analysis of this issue concluded that *CDKN2A/INK4A* aberration is a strong negative prognostic factor.[474]

---

A number of other molecular markers have been proposed to have prognostic impact in Ewing sarcoma. In one study telomerase activity in the peripheral blood during follow-up, but not at initial diagnosis, was strongly associated with disease recurrence.[255] None of the patients in this study with low telomerase activity during follow-up had disease recurrence. CD56 co-expression has been reported to be a favorable prognostic indicator in one series.[475] One report suggested that serum IGF-1R levels were prognostic,[476] although two other studies found no prognostic impact of IGF-1R levels.[477,478] Two studies identified expression of the genes encoding glutathione S-transferases, enzymes involved in chemotherapy metabolism, as novel prognostic factors.[165,479]

TREATMENT OF PATIENTS WITH NONMETASTATIC EWING SARCOMA

Local Control

Patients with nonmetastatic Ewing sarcoma require aggressive multimodality therapy to achieve long-term disease control. Local control of the primary tumor plays a key role in modern treatment for these patients. Historically, patients received radiation therapy alone as local control. Surgical local control was less commonly used because therapy was generally viewed as palliative. With improved outcomes thanks to chemotherapy, however, the late effects of radiotherapy on long-term survivors of Ewing sarcoma became apparent. In addition, limb-salvage surgical techniques became more advanced. As a result, surgical local control of resectable tumors has become the standard of care. Radiotherapy for local control of the primary tumor is now generally reserved for unresectable tumors or tumors that have been resected with inadequate margins. This section reviews the principles of radiotherapy and surgical resection in the care of patients with Ewing sarcoma.

Surgical resection is generally recommended for those tumors deemed completely resectable with wide or radical margins. For extremity tumors, surgical resection may take the form of an amputation or a limb-sparing procedure. Rotationplasty is another option for patients with femoral tumors.[383] Technical advances, such as expandable implanted prostheses, have made limb-sparing procedures increasingly appealing.[383,480] However, the choice of a limb-sparing procedure over other surgical options must not compromise the adequacy of the resection.[383] Tumor infiltration of surrounding neurovascular structures, muscle, or skin should raise concern that a limb-sparing procedure will not result in the desired wide resection.[383] Often neoadjuvant chemotherapy will produce sufficient response to allow for limb salvage when this option did not appear feasible at initial presentation.[383] In a cooperative group analysis of chest wall tumors, resection after neoadjuvant chemotherapy was associated with higher rates of negative margins compared to initial resection.[481] However, data from a single institution suggested that neither the likelihood of an adequate margin nor the overall outcome differs between patients who had surgical resection at initial diagnosis compared with patients who had surgical resection after a period of neoadjuvant chemotherapy.[482,483] Nevertheless, most available data support the current standard approach of neoadjuvant chemotherapy before planned surgical resection.

Investigators from the CESS group and the Rizzoli Institute evaluated the impact of surgical margins on outcome in Ewing sarcoma in two retrospective case series.[484,485] These groups both reported the rate of obtaining an adequate surgical margin as approximately 75%, among those patients selected for planned definitive resection.[484,485] Both groups observed that an adequate margin is more difficult to obtain in axial tumors. For example, the Rizzoli group reported that approximately one quarter of the extremity tumors treated with a limb-salvage procedure had inadequate margins. In contrast, none of the paraspinal or sacral tumors in their large series of surgically treated patients had an adequate margin.[484] The Rizzoli group observed that the 5-year event-free survival rate was higher for patients with an adequate surgical margin, although this finding may reflect improved outcome with smaller, more resectable tumors.[484] In both series a small group of patients with inadequate surgical margins did not receive postoperative radiotherapy. Only 14% to 21% of these patients experienced a local recurrence.[484,485] However, the risk of local recurrence was diminished by the addition of postoperative radiotherapy, which is the current standard practice.

Radiation therapy alone can provide adequate local control in Ewing sarcoma. In fact, the radiosensitivity of these tumors was one of the early characteristics that distinguished Ewing sarcoma from osteosarcoma.[1] Local control rates with definitive radiation therapy in large series have been reported to range from 53% to 86%.[486] For patients treated with radiation therapy alone, axial tumors (particularly pelvic tumors) have a higher rate of local failure than extremity tumors.[436,487-489] One group reported that patients with metastatic disease treated with radiation alone or surgery plus radiation have a higher rate of local failure compared with patients who have nonmetastatic disease.[490]

Several studies have evaluated the appropriate treatment volume, dose, timing, and schedule of radiotherapy in Ewing sarcoma. The IESS-1 study group reported on their experience with radiotherapy.[488] All patients received radiotherapy as the mode of local control in this study. Across the range of doses administered (30 Gy to more than 60 Gy), no differences in local failure rates were observed, although very few patients received less than 40 Gy. Most patients received radiation to the whole bone involved with tumor, but some patients were treated with more limited fields. Patients who received radiotherapy to the primary tumor plus a 5-cm margin had the same local failure rate as patients treated with whole bone radiotherapy (8% for both groups). Patients treated with less than a 5-cm margin had an inferior local control rate.

The Pediatric Oncology Group conducted a study from 1983 and 1988 with the specific aim of determining the appropriate radiation volume for patients with Ewing sarcoma of the bone.[487] Patients with tumors in expendable bones were recommended for surgical resection. Other patients were randomized to receive whole bone irradiation or involved field radiation. Patients treated with whole bone irradiation received 39.6 Gy to the entire bone containing tumor plus a boost to 55.8 Gy to the tumor with a 2-cm margin. Patients treated with involved field radiation received 55.8 Gy to the tumor with a 2-cm margin. Because of enrollment issues, 20 patients were randomized to whole bone radiation and 20 patients to involved field radiation. An additional 54 patients were nonrandomly assigned to involved field radiation. The 5-year event-free survival rate did not differ between patients randomized to whole bone radiation and patients randomized to involved field radiation (37% and 39%, respectively). The local control rate was 53% in both treatment arms. Of note, patients who received radiotherapy according to protocol guidelines for dose and volume had a superior local control rate (80%) compared with patients with major deviations (16% local control rate) or minor deviations (48% local control rate). Deviations in treatment volume seemed to be more critical. These results indicate that involved field radiation is an acceptable mode of local control for these patients but that treatment to the initial tumor volume plus an adequate margin is necessary.

Several retrospective single-institution case series have evaluated the impact of radiation dose on local control in Ewing sarcoma.[490-492] In one series patients treated with less than 49 Gy had a 5-year local control rate of 37% compared with 89% for patients treated with 49 Gy or more.[491] In this study higher doses seemed particularly important for larger tumors. In another series patients with larger tumors had a uniform local failure rate regardless of radiation dose, whereas patients with smaller tumors treated with more than 40 Gy had a higher local control rate compared with patients who had smaller tumors treated with less than 40 Gy.[492] A third case series reported no difference in outcome between patients treated with radiation doses above and below 54 Gy.[490] The CESS-81 trial randomized extremity tumors to receive 46 Gy or 60 Gy. The local failure rate was similar in these two groups.[431]

Three studies have specifically commented on the use of lower-dose radiotherapy.[462,493,494] The first study administered approximately 30 Gy in patients mainly in conjunction with some type of surgical resection, although five patients received radiotherapy only.[493] No local failures were noted in this group. The other two studies administered 30 to 36 Gy as definitive local control to patients with an objective response to neoadjuvant chemotherapy.[462,494] This strategy resulted in an unacceptably high local failure rate.

The timing of radiotherapy may be important for patients receiving definitive radiotherapy and not for patients receiving radiotherapy after surgery. A retrospective analysis of patients treated with surgery followed by radiation therapy in the CESS-86 and EICESS-92 trials demonstrated that the interval between surgery and radiation did not affect the local control rate or event-free survival rate, even up to intervals beyond 90 days.[495] In contrast, a retrospective analysis of patients with pelvic Ewing sarcoma suggested that initiating definitive radiotherapy earlier may result in a lower local failure rate.[496] A pooled analysis has also suggested that longer periods (15-18 weeks) of neoadjuvant chemotherapy before starting radiation therapy may have a negative impact on the overall survival rate.[497]

Two retrospective case series evaluated hyperfractionated radiotherapy in the management of Ewing sarcoma.[490,498] Both series concluded that local control rates were not improved by hyperfractionation. One group reported better functional results with the hyperfractionated schedule.[498] The CESS-86 trial randomized patients to conventional or hyperfractionated radiation schedules.[499,500] Patients on the conventional schedule had chemotherapy held during radiotherapy, while patients on the hyperfractionated schedule continued to receive chemotherapy during radiation. For patients treated with radiotherapy alone, the local control rate was 82% for patients on the conventional schedule and 86% for patients on the hyperfractionated schedule. The radiation schedule did not affect overall or relapse-free survival rates. The radiation schedule did not affect disease control in patients treated with surgery followed by radiation.[500]

On the basis of this experience with radiotherapy for Ewing sarcoma, current practice is for patients with unresectable tumors to receive definitive radiotherapy after 4 to 6 cycles of chemotherapy. Most groups administer 54.4 to 60 Gy as definitive radiotherapy. Patients typically receive treatment as 45 Gy to the pretreatment volume plus a safety margin of at least 2 cm followed by a boost to full-dose radiotherapy to the treatment volume remaining after neoadjuvant chemotherapy.[486] Tumors with soft tissue extension, but not infiltration, into the chest or pelvic cavities often receive treatment to the postchemotherapy volume plus a safety margin. Some centers advise full-dose preoperative radiotherapy to tumors that may become fully resectable with such therapy. Patients with inadequate surgical margins are recommended to receive postoperative radiation. The EURO-EWING group also recommends postoperative radiotherapy for patients with adequate surgical margins and a poor histologic response to chemotherapy, although this practice is not standard in North America. The EURO-EWING group recommends a hyperfractionated schedule of radiotherapy, whereas the standard in North America remains conventional fractionation.

Several groups have compared the three available modes of local control: surgery, definitive radiation, and surgery plus radiation. Several studies have clearly documented that patients who undergo surgical resection have higher local control rates or improved overall outcomes (or both) compared with patients who receive definitive radiotherapy only.* These studies must be interpreted with caution because of the presence of confounding by indication. For example, because small extremity tumors are typically selected for surgery and large axial tumors are typically managed with radiotherapy alone, the outcome between these two groups might be expected to differ on account of reasons other than the chosen mode of local control. Indeed, not all studies have concluded that surgery provides superior disease control compared with radiation. A retrospective single-institution study of 76 patients with nonmetastatic Ewing sarcoma concluded that the overall survival rate and the rate of local control were equivalent between patients who received local control as surgery, radiation, or surgery plus radiation, although the power to detect a difference may have been limited by the small size of this study.[502] A secondary analysis of data from the United Kingdom Children's Cancer Study Group (UKCCSG) ET-2 trial reached the same conclusion.[503] In addition, the overall rate of disease recurrence did not differ between local control groups. In the SE 91-CNR Italian cooperative group trial, the 3-year event-free survival rates did not differ between patients who received surgery alone and those who received radiotherapy alone.[434]

Although a randomized trial might resolve the issue of optimal mode of local control, such a randomization would be untenable to patients. Instead, several analyses have evaluated this issue by attempting to control for the known confounding factors influencing both outcome and choice of local control modality. An analysis from the Rizzoli Institute showed that patients treated with definitive radiotherapy had inferior event-free survival rates compared with patients who received surgery alone, even after controlling for age, tumor size, and serum LDH level.[484] This group did not control for tumor site in this analysis. Two similar previous analyses by this same group controlled for tumor site, among other factors.[336,348] In these analyses patients treated with radiotherapy did not have an increased risk of relapse. The EICESS/CESS experience with local control has also been retrospectively reviewed in several analyses.[500,501] On univariate analyses, these studies have demonstrated that patients treated surgically have improved local control compared with patients treated with definitive radiotherapy. Although this group has not reported a multivariate analysis of outcome based on local control, they have reported a subgroup analysis based on tumor size (above and below 100 cm^3) and site (axial versus appendicular).[501] Patients treated with radiation alone had inferior local control for all combinations of tumor size and site except small central tumors. However, patients treated with surgery appeared to have a higher rate of systemic failure compared with patients treated with radiation alone, such that the overall rate of disease recurrence was the same between groups.[485,501] This finding has not been reported by other groups. An analysis of 220 patients treated at St. Jude Children's Research Hospital also demonstrated that surgical resection was associated with lower rates of local failure, even after controlling for tumor size and year of treatment.[504] This analysis did not control for tumor site, however. Significantly, this analysis and a prospective randomized trial demonstrated lower rates of local failure in patients treated with more modern chemotherapy regimens that included ifosfamide and etoposide.[352,504]

Systemic Treatment with Chemotherapy

The use of chemotherapy for patients with Ewing sarcoma has revolutionized the care of these patients. Before the 1970s, standard therapy for this disease consisted solely of local control directed at the primary tumor. Most patients treated in this manner ultimately died from local or systemic recurrent disease.[505-507] In one series patients treated with local control alone had a median survival rate of 11 months.[506] In the 1960s and 1970s, evidence emerged that systemic chemotherapy could prevent recurrent disease in a substantial number of patients with Ewing sarcoma. This section reviews the development of modern chemotherapy regimens for this disease. Table 61-3 lists major chemotherapy regimens evaluated for Ewing sarcoma along with abbreviations for these regimens. Table 61-4 summarizes the major cooperative group trials that have contributed to current treatment approaches to this disease.

Early Improvements with Vincristine, Actinomycin-D, Doxorubicin, and Cyclophosphamide

Given the poor outcomes observed with local control alone, investigators began using single-agent chemotherapy for Ewing sarcoma. Although single-agent therapy did not substantially improve the long-term outcomes for these patients, these studies did identify a group of drugs capable of inducing tumor regression. Some of the most effective agents included vincristine, actinomycin-D, doxorubicin, and cyclophosphamide. Very quickly, investigators began to evaluate the use of these drugs in combination for patients with Ewing sarcoma.

One group evaluated two different combinations: vincristine with cyclophosphamide given in 8-week cycles for five cycles and vincristine, actinomycin-D, doxorubicin, and cyclophosphamide (VACA) given in weekly components for 18 months.[506] Most patients received

radiotherapy as the mode of local control. In both regimens chemotherapy and radiotherapy started simultaneously at the initiation of treatment. Patients who received either regimen had a statistically significant improvement in outcome compared with historical controls who received only local control, suggesting that the VACA regimen resulted in better outcomes than the vincristine-cyclophosphamide regimen.

Another group reported on 30 patients with nonmetastatic Ewing sarcoma treated with 18 months of vincristine, doxorubicin, cyclophosphamide, and procarbazine.[507] Chemotherapy and radiotherapy were given concurrently at the start of therapy. The 6-year disease-free survival rate was 49%, which was a substantial improvement on outcomes in historical controls treated with radiotherapy alone.

The Memorial Sloan Kettering Cancer Center treated 20 patients with localized Ewing sarcoma with 18 to 20 months of VACA as adjuvant therapy.[508] The cumulative dose of doxorubicin used in this study typically exceeded 500 mg/m^2, higher than in most other studies. The 5-year disease-free survival rate was 75%, perhaps highlighting the sensitivity of Ewing sarcoma to doxorubicin. The cardiotoxicity associated with these doses of doxorubicin resulted in a reduction in the cumulative doxorubicin exposure in subsequent studies by this group.[509]

The St. Jude Children's Research Hospital evaluated the use of neoadjuvant therapy with cyclophosphamide and doxorubicin for five cycles. An early report of this regimen reported that 19 of 23 evaluable patients had a complete response to therapy.[510] After these five cycles of neoadjuvant therapy, patients received local control, usually with radiotherapy. With the start of local control, patients began adjuvant therapy with vincristine and actinomycin-D for approximately 11 weeks followed by an additional six cycles of cyclophosphamide and doxorubicin. At the time of a follow-up report of 50 evaluable patients with nonmetastatic disease treated in this manner, 17 patients had developed recurrent disease.[462] A larger cooperative group study evaluating radiotherapy in Ewing sarcoma used a similar chemotherapy regimen and reported a 5-year event-free survival rate of 51% in patients with nonmetastatic disease.[487]

The Rizzoli Institute performed a series of trials evaluating both adjuvant (after local control) and neoadjuvant (before local control) VACA regimens. In the first trial patients received adjuvant therapy with vincristine, doxorubicin, and cyclophosphamide (VDC) for 2 years.[505] At the time of diagnosis, patients began chemotherapy in concert with local control of the primary tumor. In the 85 patients with localized disease treated in this manner, the 5-year event-free survival rate was 34%.[342] In contrast, only 5% of historical controls treated with local control only remained continuously free of disease.[505] The successor study treated 59 patients with localized disease with 18 months of VACA.[511] In this study the 5-year event-free survival rate was 59%, suggesting a benefit to the addition of actinomycin-D. The next study by this group evaluated VDC given as three neoadjuvant cycles followed by VACA chemotherapy after local control for a total of 15 months.[342,512] The 5-year event-free survival rate for the 108 patients with localized disease treated in this study was 49%. Compared to VACA given exclusively as adjuvant therapy, this result suggests that the change to neoadjuvant therapy did not improve outcomes for these patients.

Based on these promising results, several cooperative groups set out to evaluate vincristine, actinomycin-D, and cyclophosphamide (VAC) and VACA regimens in large groups of uniformly treated patients. IESS-1 was the first randomized study in patients with Ewing sarcoma.[435] This study enrolled patients from 1973 and 1978. The 342 patients with nonmetastatic Ewing sarcoma were randomized to one of three treatment arms. Patients in the first and second treatment arms received VAC, with patients in the second treatment arm also receiving prophylactic whole lung irradiation. Patients in the third treatment arm received VAC plus doxorubicin. Patients in this arm received doxorubicin every 12 weeks and actinomycin-D every 12 weeks, such that they received one of these agents every 6 weeks. Patients in the VAC arms received actinomycin-D every 12 weeks. All patients received radiotherapy to the primary tumor. Patients who received doxorubicin had a 5-year relapse-free survival rate of 60% compared with only 24% for patients who received VAC only. Patients who received VAC with whole lung irradiation had an intermediate 5-year relapse-free survival rate of 44%. These results indicated that the addition of doxorubicin to VAC significantly improved outcomes compared with either VAC alone or VAC with whole lung irradiation. The contribution of increased dose intensity in the doxorubicin arm to this improved outcome is not clear. Subgroup analysis showed that outcomes were inferior for patients with pelvic primary tumors and did not differ by treatment arm for these patients. Doxorubicin performed as well as whole lung irradiation in preventing lung metastasis. Based on these results, four-drug therapy with VACA became the standard chemotherapy approach for patients with Ewing sarcoma.

The IESS-2 study expanded on these results by randomizing patients with nonmetastatic disease not involving the pelvis to two different VACA dosing schedules.[513] Patients on one schedule received cycles of therapy every 3 weeks, and patients on the other schedule received more moderate doses of the same drugs at more frequent intervals. All patients received treatment for approximately 20 months. A total of 214 patients were enrolled in this study from 1978-1982. The 5-year relapse-free survival rate for patients with nonpelvic tumors who received higher-dose intermittent VACA was 73%, compared with 56% for patients who received more protracted VACA. Overall survival rate results showed a similar pattern. These results indicated a significant survival advantage for the higher-dose intermittent dosing schedule, at least for patients with tumors arising outside the pelvis.

The first German cooperative group trial for this disease (CESS-81) also used VACA administered in 3-week cycles.[431] This trial enrolled 93 patients with nonmetastatic disease from 1981 to 1985. Treatment duration was only 10 months, which was shorter than treatment on the IESS protocols. The 5-year disease-free survival rate was 55%, including patients with pelvic tumors. This result is similar to the outcome of VACA-treated patients on IESS-1, which also included patients with pelvic tumors. This result suggested that a shorter treatment duration using higher-dose regimens every 3 weeks does not compromise outcome.

The first Ewing sarcoma study of the United Kingdom Children's Cancer Study Group (UKCCSG ET-1) sought to standardize the treatment of newly diagnosed Ewing sarcoma using VACA-based chemotherapy.[343] This nonrandomized trial enrolled 142 patients from 1978 to 1986. Patients received one or two induction cycles of chemotherapy with VDC. Local therapy, with a preference for definitive radiotherapy, occurred next while patients received weekly cyclophosphamide and vincristine. Patients then received cycles of VDC alternating every 3 weeks with VAC for a total of 1 year of therapy. The 5-year relapse-free survival rate was 41%, and the 5-year overall survival rate was 44% for patients with nonmetastatic disease. The study authors suggest that the inferior outcome in this trial compared with that of other VACA-based trials at the time may have been due in part to decreased early doxorubicin dose intensity.[343]

The first French cooperative group study of Ewing sarcoma also used VACA-based chemotherapy as well as radiotherapy as the preferred mode of local control.[437] This study enrolled 95 patients between 1978 and 1984. Patients received cycles of VDC alternating with VAC for a total of 16 months of treatment. The 4-year disease-free survival rate for patients with nonmetastatic disease was 52%.

A follow-up French cooperative group study (EW88) enrolled 141 patients with nonmetastatic disease from 1988 to 1991.[347] This study administered cyclophosphamide in a more protracted manner, following a regimen piloted at St. Jude's Children's Research Hospital in the 1970s. Patients received initial chemotherapy with cyclophosphamide given daily for 7 days followed by doxorubicin on day 8. Patients received five cycles of this therapy before proceeding to local control. Surgery was recommended when possible. Radiotherapy was reserved for patients with unresectable tumors, incompletely resected tumors, or tumors with more than 5% viable tumor after initial chemotherapy. Following local control, patients received vincristine and actinomycin-D for 12 weeks followed by six additional cycles of cyclophosphamide and doxorubicin using the same schedule used neoadjuvantly. Administering these standard four drugs in this manner resulted in a 5-year disease-free survival rate of 58%.

Addition of Ifosfamide and Ifosfamide with Etoposide to VACA-Based Therapy

An initial report from the U.S. National Cancer Institute (NCI) demonstrated a response rate of 45% in 20 patients with recurrent Ewing sarcoma treated with a 5-day course of ifosfamide.[514] A follow-up study by this group evaluated ifosfamide combined with etoposide (IE) for patients with recurrent pediatric tumors.[515] Of the 17 evaluable patients with recurrent Ewing sarcoma included in the preliminary report, 16 patients had a partial response to therapy, for a response rate of 94%. A larger cooperative group study sponsored by the Pediatric Oncology Group included 55 patients with recurrent Ewing sarcoma treated with ifosfamide and etoposide.[516] The response rate in this study was 25%. Based on these promising results in patients with recurrent disease, the St. Jude Children's Research Hospital evaluated IE in patients with newly diagnosed high-risk disease.[517] This group gave three cycles of IE as an initial window before proceeding with doxorubicin and cyclophosphamide chemotherapy. Only 1 of 26 patients failed to respond to IE, for a response rate of 95%.

A number of single-institution studies incorporated ifosfamide and etoposide into the VACA backbone of therapy for newly diagnosed patients. One study from the NCI administered IE alternating with VDC or VAC for a total of 18 3-week cycles.[518] Ifosfamide was administered both before and after local control. A total of 31 patients with nonmetastatic disease were treated and had a 5-year event-free survival rate of 64%. This outcome was significantly better than historical controls with nonmetastatic disease treated with VDC and total body irradiation with stem cell rescue. Two studies from the Rizzoli Institute introduced ifosfamide at different times and reached different conclusions. In the REN-2 study, patients with localized disease received ifosfamide for the first time after local control.[512] The cumulative ifosfamide dose was 54 grams/m^2. The 5-year event-free survival rate for the 82 patients treated was 51%. This result was not different from historical controls treated with VACA-based therapy. In the REN-3 study, ifosfamide was introduced before local control with the cumulative dose held constant at 54 grams/m^2.[342] The 157 patients with nonmetastatic disease had a 5-year event-free survival rate of 71%, which was significantly better than any of the previous chemotherapy regimens evaluated at their center. These results suggest that early introduction of ifosfamide may improve outcome.

Several cooperative group studies have evaluated the efficacy of ifosfamide both with and without etoposide. One of the first cooperative group studies incorporating ifosfamide was the second French cooperative group study of Ewing sarcoma.[335] Patients enrolled from 1984 to 1987 and received initial therapy with alternating 3-week cycles of vincristine, actinomycin-D, and ifosfamide (VAI) and vincristine, doxorubicin, and ifosfamide (VDI) for a total of six cycles. Patients then underwent local control, with a preference for complete surgical resection. All patients were to receive radiotherapy, with the dose dependent on the extent of surgical resection. During radiotherapy patients received two cycles of vincristine with doxorubicin and two cycles of vincristine with ifosfamide. Following local control, patients received alternating 3-week cycles of VAI and vincristine with doxorubicin to complete a total of 1 year of therapy. The 5-year disease-free survival rate was 52% for 95 patients with nonmetastatic disease. This result prompted this group to conclude that substituting ifosfamide for cyclophosphamide did not improve outcomes. In addition, patients in this study had a higher than expected incidence of diminished cardiac function, prompting early closure of the study.

The CESS-86 trial was the first cooperative group attempt to risk-stratify patients and alter therapy based on risk.[433] Patients with small (less than 100 mL tumor volume) extremity tumors received VACA given as 3-week cycles for 36 weeks. Patients with large (100 mL or greater) tumors or axial tumors received identical therapy except ifosfamide was substituted for cyclophosphamide (VAIA). For the 301 nonmetastatic patients treated on this study, the ten-year event-free survival did not differ between patients who received VACA or VAIA (49% and 53%, respectively). However, multivariate analysis demonstrated that, controlling for tumor size and site, VACA chemotherapy was less effective than VAIA.

The French EW-93 study prescribed doxorubicin and cyclophosphamide for all patients with localized disease and reserved IE for patients with a poor response to three cycles of that therapy.[519] Patients with less than 50% regression of soft tissue mass on first evaluation were nonrandomly assigned to receive two cycles of IE before surgical resection. Of 214 patients, 33 received IE, and only eight of these refractory patients responded to IE before local control measures.

The UKCCSG ET-2 study evaluated the substitution of ifosfamide for cyclophosphamide in newly diagnosed patients.[436] This nonrandomized trial enrolled 243 patients from 1987 to 1993. Patients received VDI for four 3-week cycles before undergoing local control. In contrast to ET-1, ET-2 suggested a preference for surgery as mode of local control. Following local control, patients received VAI to complete 1 year of therapy. Patients received a cumulative doxorubicin dose of 420 mg/m^2 and cumulative ifosfamide dose of 114 grams/m^2. The 5-year relapse-free survival rate was 62% for patients with nonmetastatic disease. These results demonstrate a substantial improvement over the results of the UKCCSG ET-1 study. These improvements may be due to increased doxorubicin dose intensity, use of ifosfamide, preference for surgery as local control, or a combination of these factors.

An Italian cooperative group study (SE 91-CNR) enrolled 160 evaluable patients with nonmetastatic Ewing sarcoma from 1991 to 1997.[434] Patients treated on this protocol received initial therapy with alternating 3-week cycles of VDC and VAI. After 24 weeks of therapy, patients received alternating 3-week cycles of IE and VAC to complete 36 total weeks of therapy. Surgery was the preferred mode of local control for resectable tumors. The 5-year event-free survival rate was 69.4%.

A Scandinavian Sarcoma Group trial (SSG IX) enrolled patients with metastatic and nonmetastatic Ewing sarcoma from 1990 to 1996.[344] All patients received 35 weeks of chemotherapy given as 3-week cycles. Patients received cycles of VDI every 3 weeks, with cisplatin, doxorubicin, and ifosfamide substituted at cycles 2, 5, 8, and 11. Surgery was the preferred mode of local control. The 5-year metastasis-free survival rate was 58% for the 73 patients with initially nonmetastatic disease. The 5-year overall survival rate for these patients was 70%. The 5-year overall survival rate for patients presenting with metastatic disease was 28%. These results compare favorably to those from other contemporary trials.

Two randomized cooperative group trials have directly compared VACA-based chemotherapy to ifosfamide-containing chemotherapy. The North American intergroup study INT-0091 enrolled 518 patients with metastatic and nonmetastatic Ewing sarcoma from 1988 to 1992.[352] The standard arm on this study consisted of 3-week cycles of VDC. The experimental arm consisted of 3-week cycles of VDC alternating with IE. In both treatment arms, actinomycin-D was substituted for doxorubicin after a cumulative doxorubicin dose of 375 mg/m^2. All patients received 17 cycles of therapy, for a total study duration of 49 weeks. Local control occurred at week 12 of the therapy, with mode of local control determined on an individualized basis. The addition of IE significantly improved the outcome for patients with nonmetastatic disease, with a 5-year event-free survival rate of 69% compared with 54% for patients receiving VDC only. The incidence of local failure was also lower for patients who received IE, indicating that improved systemic therapy also improves local control. Based on these results, the combination of VDC and IE has become the standard therapy for patients with nonmetastatic Ewing sarcoma treated in North America.

The EICESS-92 study represents a collaborative effort between the UKCCSG and German cooperative groups. This trial enrolled 647 patients with either localized and metastatic Ewing sarcoma from 1992 to 1999. Patients with small (less than 100 mL tumor volume) localized tumors were deemed standard risk. These patients received initial chemotherapy with VAIA given as 3-week cycles followed by a randomization between continued VAIA or VACA. All other patients were deemed high risk and were randomized to receive VAIA or VAIA plus etoposide. Among standard-risk patients there were no statistically significant differences in event-free or overall survival rates between the randomized arms, although it is important to note that all patients received ifosfamide before randomization.[520] Among high-risk patients there were trends suggesting improved outcomes with the addition of etoposide to VAIA, although no statistically significant differences were found.

Dose-Intensified VACA/IE Regimens

The next generation of chemotherapy regimens emphasizes increasing the dose intensity of known active agents in this disease. The P6 protocol from the Memorial Sloan Kettering Cancer Center used an augmented dose of cyclophosphamide given in combination with vincristine and standard-dose doxorubicin.[521] Patients received a total of seven cycles of alternating VDC and IE along with local control of the primary tumor. The 4-year event-free survival rate for the 44 patients with localized disease was 82%, suggesting an improvement in outcome with higher-dose cyclophosphamide.

Two recent North American cooperative group studies have investigated strategies for dose-intensifying therapy. The first trial, known as INT-0154, included 478 eligible patients with nonmetastatic Ewing sarcoma diagnosed from 1995 to 1998.[438] Patients were randomized at study entry to receive alternating 3-week cycles of VDC and IE using either a dose-intensified or standard-dose approach. The standard-dose arm emulated the therapy given to patients assigned to the experimental arm of INT-0091. Patients in the dose-intensified arm received higher individual doses of the alkylating agents than patients in the standard-dose arm, but cumulative drug doses were approximately equivalent between arms. Patients in the dose-intensified arm completed therapy in 30 weeks, whereas patients in the standard-dose arm completed therapy in 48 weeks. Dose-intensified treatment did not improve event-free or overall survival rates and was associated with increased toxicity, such that this approach is not recommended for this population.

In Children's Oncology Group (COG) protocol AEWS0031, 568 patients with nonmetastatic Ewing sarcoma were randomized at study entry to receive cycles of standard-dose VDC and IE alternating every 3 weeks or every 2 weeks.[522] Individual and cumulative drug doses were equivalent between treatment arms. All patients received 14 cycles of therapy, requiring 42 weeks in standard arm and 28 weeks in the interval compression arm. Interval compression was feasible, with a median cycle length of 15 days in the interval compression arm. Patients randomized to the interval compression arm had a superior event-free survival rate compared with patients randomized to the standard arm (73% versus 65% at 5 years). Toxicity was equivalent between both arms. Based on these findings, this approach has been adopted in North America as a standard practice for patients with localized Ewing sarcoma.

Several groups have evaluated chemotherapy regimens that combine multiple active agents given together during a cycle of therapy. In a protocol at St. Jude Children's Research Hospital, 51 patients with Ewing sarcoma received ifosfamide, etoposide, cyclophosphamide, and doxorubicin given together for three cycles before local control.[523] Patients then received alternating cycles of IE and cyclophosphamide with doxorubicin for a total of 41 weeks of therapy. The doses of ifosfamide, etoposide, and cyclophosphamide given after local control were higher than in previous studies. Patients were able to complete the planned neoadjuvant therapy, but myelosuppression limited the ability of patients to receive the planned adjuvant therapy on schedule. Specifically, only 66% of patients received all planned chemotherapy, and only 25% of patients received all planned chemotherapy on schedule. Despite difficulties in achieving the desired degree of dose intensification, outcomes remained favorable. The 3-year event-free survival rate for patients with localized disease was 78%.

A British group has piloted the use of vincristine, ifosfamide, doxorubicin, and etoposide (VIDE) as neoadjuvant therapy for this disease.[524] In this study 30 patients with newly diagnosed Ewing sarcoma were treated with six 3-week cycles of VIDE. Because of hematologic toxicity, etoposide was dose reduced or omitted from 50% of the planned cycles. All attempts at collecting peripheral blood stem cells after a cycle of VIDE were successful. Of the 24 patients evaluable for radiographic response, only one patient had progressive disease. Patients in this pilot study received additional therapy following local control. The final results of this study are not yet available.

The European cooperative groups have initiated a combined trial known as EURO-EWING 99 that relies on VIDE as neoadjuvant therapy. All patients receive initial treatment with six 3-week cycles of VIDE. This trial then tailors therapy according to risk. Patients with small (less than 200 mL tumor volume) nonmetastatic tumors with good chemotherapy response are randomized to receive additional therapy with seven cycles of VAC or VAI. Patients with large tumors, pulmonary metastases, or poor chemotherapy response are randomized to receive additional therapy with seven cycles of VAI or high-dose therapy with stem cell rescue (discussed later). This randomized trial is ongoing.

Two nonrandomized trials have reported on the use of high-dose chemotherapy as a consolidation strategy for patients with localized Ewing sarcoma and adverse prognostic factors. In the French EW93 trial, patients with localized Ewing sarcoma were considered high risk if they had either a 30% or greater viable tumor at time of surgical resection or a 50% or less reduction in tumor volume by imaging for patients not candidates for surgical resection.[519] These patients were nonrandomly assigned to receive high-dose chemotherapy with busulfan and melphalan. There were 48 patients who were classified as high risk, 34 of whom received high-dose chemotherapy. For the entire cohort of patients with high-risk disease, the 5-year event-free survival rate was 48%. A joint Italian-Scandinavian protocol adopted a similar approach, with busulfan and melphalan high-dose chemotherapy prescribed for patients with localized disease and macroscopic foci of tumor at the time of surgery or incomplete regression of soft tissue masses in patients not candidates for surgical resection.[525] Outcomes for the 126 patients with these poor risk features who received high-dose therapy were similar to those of patients without poor risk features who did not receive high-dose therapy. Given the nonrandomized study designs and risk of selection bias for patients who proceeded to high-dose therapy in these two trials, the role of this approach in patients with localized Ewing sarcoma remains unclear.

Management of Tumors Arising at Special Sites

Pelvic Ewing Sarcoma

Ewing sarcoma frequently arises in the pelvis. These pelvic tumors tend be large and associated with crucial viscera, nerves, and bones (particularly of the acetabulum), making complete surgical resection difficult. The local failure rate for patients with pelvic primary tumors ranges from 15% to 27%, which is higher than the local failure rate typically reported in appendicular tumors.[526-530] In one large series, even after exclusion of patients with a local relapse, the outcome for patients with pelvic primary tumors was still inferior to outcomes at other sites.[527] This result suggests that both systemic control and local control are inadequate for these patients.

Recognizing the poor outcome of patients with pelvic primary tumors, the IESS-2 trial nonrandomly assigned patients to the higher-dose intermittently scheduled VACA arm of that study.[531] In addition, an increased emphasis was placed on surgical control of pelvic tumors. With this strategy, patients with pelvic tumors had a 5-year relapse-free survival rate of 55% compared with only 23% for patients in the IESS-1 trial. Because the higher dose VACA arm resulted in better outcomes in the randomized nonpelvic patients treated in IESS-2, the improvements in outcome seen in patients with pelvic tumors may have been attributable to better systemic control, better local control, or both. Indeed, patients with pelvic tumors in IESS-2 were more likely to undergo complete surgical resection and had a lower local failure rate compared to patients with pelvic tumors in IESS-1. Compared with patients who did not have a complete resection, complete resection did not improve the overall or relapse-free survival rate in these patients in IESS-2.[531]

The optimal mode of local control for pelvic tumors has been difficult to determine with rigorous studies. A report from the Mayo Clinic found that patients with pelvic Ewing sarcoma treated with surgery had a statistically significant superior overall survival rate compared with patients treated without surgery.[532] In several other series of patients with pelvic primary tumors, the mode of local control has not clearly been shown to affect outcome,[527-529,533] although some trends have suggested improvements in survival rates among patients treated surgically.[528,529,533] Some groups have also reported a trend toward a lower local recurrence rate in patients treated surgically,[496,527,528,532] although not all groups have reported this trend.[529] The results of these studies are often difficult to evaluate insofar as patients treated with complete surgical resection typically have small resectable tumors. However, two groups have attempted to control for this and other confounding factors. The French cooperative group reported on 53 patients with pelvic Ewing sarcoma.[534] After controlling for size and other potential confounding factors, researchers found that patients treated with radiotherapy alone had an increased risk of recurrence and death compared with patients who received surgery or surgery with radiotherapy. The COG retrospectively analyzed 75 patients with pelvic primary tumors treated on INT-0091.[530] In contrast to the results of the French group, the mode of local control did not affect event-free survival or local failure rates after controlling for confounding factors such as size. As observed in the main analysis of all tumor sites, patients with pelvic tumors who were randomized to receive VACA plus IE on this study had a lower risk of local failure compared with patients randomized to receive VACA alone.[530] Given this uncertainty and the risk of second tumors from radiotherapy, many groups choose to resect pelvic tumors that can be resected without functional consequences. For tumors that cannot be resected without functional consequences, options include either definitive radiotherapy alone or preoperative radiotherapy with the possible addition of wide resection.

Chest Wall Ewing Sarcoma

Chest wall tumors also require specialized management, particularly insofar as these tumors often invade the pleura or have associated pleural effusions. Some data suggest that surgical resection of chest wall tumors provides superior local control, although these analyses do not account for differences in tumor size that influence resectability.[535,536] Indeed, other analyses have not shown a difference in outcome based on mode of local control for chest wall tumors.[481,537,538] Results from INT-0091 and INT-0154 indicate that neoadjuvant chemotherapy before attempted resection of a chest wall tumor increases the likelihood of obtaining negative margins compared with results from attempted resection before chemotherapy.[481,538] Delayed resection at this site therefore decreases the need for postoperative radiotherapy in these patients.[481,538] Avoiding chest wall radiation is particularly appealing given the added pulmonary and cardiac toxicities associated with this therapy.

Whereas several reports have suggested that an associated pleural effusion did not worsen outcome, patients with chest wall tumors and pleural effusions were often recommended to receive hemithorax irradiation in these studies.[536,537,539] Indeed, a report from the French cooperative group suggested that patients with rib primary tumors and an associated pleural effusion had an increased risk of local relapse without radiotherapy.[537] In the EICESS/CESS studies, patients who received hemithorax irradiation had more unfavorable features than patients who did not receive hemithorax irradiation.[540] Despite this difference, the rate of local relapse was the same in both groups, whereas the rate of systemic relapse was higher in the group of patients who did not receive hemithorax irradiation.[540] This result may be interpreted as evidence of the direct benefit of hemithorax irradiation in preventing dissemination of residual tumor cells from the pleural space. Alternatively, hemithorax irradiation may reduce the volume of lung at risk for subsequent relapse, because the IESS-1 researchers noted that whole lung irradiation can prevent lung metastasis in patients with initially nonmetastatic disease. Patients with chest wall primary tumors and positive pleural fluid cytology or pleural-based nodules treated according to the most recent COG protocol received hemithorax radiation.

Ewing Sarcoma of the Spine

Management of patients with tumors arising along the spinal column requires careful planning by a multidisciplinary team, including oncologists, radiation oncologists, orthopedic surgeons, general surgeons, and neurosurgeons. Small case series have suggested that local control and overall outcomes for patients with primary tumors at this site do not differ from outcomes for patients with tumors arising from other sites.[341,541] One group reported that sacral primary tumors fare less well than other vertebral tumors,[340] although this result was not replicated in other series.[338,339,341] The largest reported experience with vertebral Ewing sarcoma comes from the EICESS/CESS studies.[542] A total of 116 patients had tumors arising from cervical, thoracic, or lumbar vertebrae. Given the difficulties in obtaining a complete resection at this site, all but four patients received radiotherapy as part of local control of the tumor. The local failure rate for patients treated with radiotherapy alone was not significantly different from that of patients treated with surgery plus radiotherapy (22.6% and 18.7%, respectively). Local relapses typically occurred within the radiation field, suggesting that inadequate selection of radiotherapy fields was not to blame for these local relapses. Despite the fact that the spinal cord limits radiotherapy dosing at this site, the local failure rate for patients with vertebral tumors treated with radiotherapy alone was not higher than the local failure rate for patients with tumors of any location treated with radiotherapy alone.[501,542] This effect may result from the generally smaller size of paraspinal tumors compared with that of other tumors selected for local control with definitive radiotherapy. It should be noted, however, that patients with a vertebral tumor treated with radiotherapy who experience local recurrence often have few local control options because additional radiotherapy may compromise the spinal cord.[542]

Soft Tissue Ewing Sarcoma

Historically, patients with soft tissue Ewing sarcoma were not included in cooperative group clinical trials for patients with Ewing sarcoma of bone. Instead, patients with soft tissue Ewing sarcoma have often been included in protocols designed for patients with other soft tissue sarcomas, including rhabdomyosarcoma.[543,544] More recent work suggests that these patients should receive treatment following Ewing sarcoma protocols. For example, one study compared patients treated according to International Society of Paediatric Oncology (SIOP) protocol MMT89 without doxorubicin to patients treated on the French EW93 protocol with doxorubicin.[543] Although it was a nonrandomized comparison, baseline patient characteristics were similar between both groups, but event-free and overall survival rates were superior for patients treated according to the EW93 protocol. In North American study INT-0154, patients with soft tissue disease had outcomes equivalent to those of patients with skeletal primary tumors.[438] These results support the current practice of including these patients in modern trials for Ewing sarcoma.

Summary of Outcomes for Patients with Nonmetastatic Ewing Sarcoma

Patients with Ewing sarcoma have shown great improvements in outcome over the past 4 decades. For patients with localized tumors, expected survival rates have increased to greater than 70% with modern multimodality therapy. Figure 61-8 demonstrates these improvements graphically, using Surveillance, Epidemiology, and End Results (SEER) data from 1975 to 2000.[5,545] A similar pattern of steady improvement over time has also been reported using data from a large European registry.[546]

TREATMENT OF PATIENTS WITH METASTATIC EWING SARCOMA

Systemic Therapy

Despite the recognition that these patients have a poor prognosis, early studies often treated patients with metastatic disease with the same combined modality therapy used for nonmetastatic patients. Because the outcomes for these patients have not improved in concert with the gains seen in nonmetastatic patients, more aggressive strategies have been added to this backbone. These strategies are discussed here.

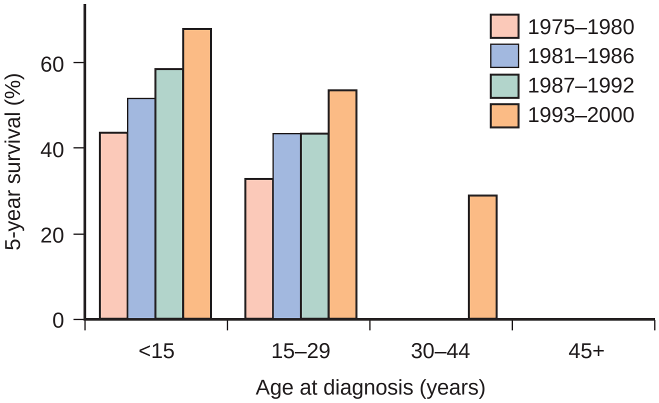

Figure 61-8 Overall survival rates at 5 years from initial diagnosis of Ewing sarcoma according to age at initial diagnosis and treatment era. *(Gurney JG, Swensen AR, Bulterys M: Malignant bone tumors. In Ries LAG, Smith MA, Gurney JG, et al, editors:* Cancer incidence and survival among children and adolescents: United States SEER Program 1975-1995, Bethesda, MD. *1999, National Cancer Institute, SEER Program, NIH Pub. No. 99-4649, p. 99–110.)*

Attempts to improve outcomes for these patients through changes in chemotherapy regimens have been largely unsuccessful. The IESS-2 study attempted to improve on the 30% 5-year overall survival rate for metastatic patients treated on IESS-1.[355] This group added 5-fluorouracil to the VACA backbone of IESS-1. As in IESS-1, radiation to all metastatic sites was prescribed. The 5-year overall survival rate was 28% despite the addition of 5-fluorouracil.[355] Single-institution studies suggested that the addition of IE to VACA did not improve the outcome for patients with initially metastatic disease.[518,521,523] The INT-0091 study confirmed these disappointing results.[352,356] INT-0091 also included a nonrandomized arm in which patients with newly diagnosed metastatic disease received dose-intensified VDC and IE.[547] Patients received higher doses of doxorubicin, cyclophosphamide, and ifosfamide compared with patients treated in the randomized portion of INT-0091. Although this was a nonrandomized comparison, the 60 patients treated with dose-intensified therapy had similar outcomes to patients with metastatic disease treated with standard-dose therapy on INT-0091. The Pediatric Oncology Group and Children's Cancer Group conducted a phase II study of alkylator-intensive chemotherapy for patients with newly diagnosed metastatic disease.[548] Patients in this study received topotecan (N=36) or topotecan and cyclophosphamide (N=37) in an upfront window. After the window phase, patients received IE alternating with VDC, with higher doses of ifosfamide and cyclophosphamide used than in standard protocols. This strategy did not improve the outcomes for these patients. A regimen developed in Seattle combines vincristine, doxorubicin, cyclophosphamide, ifosfamide, and etoposide given together each cycle.[549] All five patients with metastatic Ewing sarcoma and evaluable disease obtained a complete radiographic response to this therapy. Only one of these patients remains free of disease 33 months from initial diagnosis.

Patients with metastatic disease at initial diagnosis are candidates for novel approaches to the treatment of Ewing sarcoma. COG evaluated the addition of metronomic chemotherapy with vinblastine and celecoxib to the VACA/IE backbone used in INT-0091 in 35 patients with metastatic disease.[550] This approach used an antiangiogenic approach together with known active cytotoxic chemotherapy in an attempt to improve the outcome for these patients. This approach was feasible, although small patient numbers precluded conclusions about the impact of vinblastine and celecoxib on disease control.

Patients with metastatic disease who do not respond to initial therapy may receive second-line chemotherapy (described later, in the section on patients with recurrent disease). These patients may also be candidates for other investigational therapies, including high-dose therapy with hematopoietic stem cell rescue (discussed later).

Role of Surgery and Radiation in Patients with Metastatic Disease

Patients presenting with metastatic disease typically receive local control of their primary tumor. Because of their disseminated disease and poor prognosis, the local control strategy for these patients tends to differ from that of patients with nonmetastatic disease. In particular, patients with metastatic disease are more likely receive definitive radiotherapy for local control because they often require radiotherapy to other sites of disease. Indeed, at least one analysis has demonstrated the importance of local control measures directed against both primary and metastatic sites of disease in improving outcomes for this high-risk patient population.[551]

Whole lung irradiation appears to be an effective therapy for patients with lung metastases. The St. Jude Children's Research Hospital reported on patients at their center with lung metastases at initial diagnosis. Patients in this series received whole lung irradiation if they had residual lung metastases after initial chemotherapy. Patients in this series who received whole lung irradiation for residual lung metastases had an outcome equivalent to that of patients whose lung metastases resolved with initial chemotherapy and who did not receive whole lung irradiation.[552] The authors argue that the patients with residual lung metastases after initial chemotherapy would have had an even worse outcome without the addition of whole lung irradiation. Data from the CESS studies suggest that a dose-response relationship may exist for whole lung irradiation.[553] This group reported that patients with initial lung metastases who remained in clinical remission had received higher doses of whole lung irradiation than patients who relapsed. The number of patients reported in this series was small, but the group reported that four of ten patients who received 12 to 16 Gy remained in remission compared with five of six patients who received 18 to 21 Gy. Only one of six patients who did not receive whole lung irradiation remained in clinical remission.[553]

The strongest evidence in favor of whole lung irradiation for patients with lung metastases comes from the EICESS group. This group reported on 100 evaluable patients with isolated lung metastases, 75 of whom received 15 to 18 Gy whole lung irradiation as part of their combined modality therapy.[351] The risk of pulmonary recurrence was significantly decreased with the addition of whole lung irradiation. Moreover, the overall risk of disease recurrence diminished with this intervention. The 5-year event-free survival rate for patients treated with whole lung irradiation was 38%, compared with 27% for patients who did not receive whole lung irradiation. This result is even more striking in light of the fact that the indication for whole lung irradiation in this trial was residual lung metastasis after chemotherapy. Although whole lung irradiation was not prescribed in a randomized manner, potential confounding variables appeared to be balanced between patients who received whole lung irradiation and patients who did not receive whole lung irradiation. In addition, a Cox regression model indicated that whole lung irradiation improved the event-free survival rate after controlling for potential confounding variables.[351] An additional report from the EICESS group indicated that whole lung irradiation improves the outcome even for patients with lung metastases combined with metastases at other sites.[354] Currently, whole lung irradiation is commonly being employed for patients with lung metastases at initial presentation regardless of the radiographic response to initial chemotherapy. Patients with bone metastases also typically receive radiotherapy directed to these sites, although data supporting this strategy are lacking.

Pulmonary metastasectomy plays little role in the management of patients with lung metastases at initial diagnosis. One small case series suggested that pulmonary metastasectomy might improve the outcome for these patients, although this result was confounded by the fact that only patients with resectable lung metastases underwent resection.[554] Surgical resection of pulmonary metastases was not shown to improve outcomes in patients treated by the EICESS group who had residual lung metastases after initial chemotherapy.[351]

Role of High-Dose Therapy with Hematopoietic Stem Cell Rescue for Metastatic Disease

Patients with initially metastatic Ewing sarcoma may be candidates for high-dose therapy with stem cell rescue. The role of high-dose therapy for these patients remains unclear, with most studies relying on comparisons with historical controls consisting of patients treated without high-dose therapy. For example, a study using data from a bone marrow transplant registry observed similar outcomes between patients treated with and without high-dose therapy.[555] Numerous groups have demonstrated the feasibility of delivering myeloablative therapy as consolidation therapy after initial chemotherapy and local control in these high-risk patients. No completed studies have evaluated high-dose therapy in a randomized manner. As such, studies suggesting a benefit from this modality are subject to selection bias in which only patients with good overall physical condition who attain a certain level of disease control are considered for high-dose therapy. Results from larger single-institution and multicenter studies are summarized here.

In the late 1980s and early 1990s, two American groups investigated the use of 8 Gy total-body irradiation with autologous bone marrow rescue as consolidation for patients with high-risk Ewing sarcoma.[556,557] Patients received VDC with or without actinomycin-D as initial chemotherapy along with radiotherapy to their primary site. Patients who attained a complete response to this therapy proceeded to consolidation therapy. Despite selecting therapy-responsive patients, high-dose therapy did not improve the outcome for patients with metastatic disease. The 6-year overall survival rate for patients with metastatic disease in one study was only 14%.[557]

Two EICESS centers evaluated 12 Gy total-body irradiation combined with melphalan and etoposide as consolidation therapy in patients with bone metastases or early relapsed disease.[558,559] Patients in this series received either autologous or allogeneic transplant if they had responded favorably to initial chemotherapy. Although an initial report showed a relapse rate of only 52%, a follow-up report indicated that the event-free survival rate from the time of transplant for this cohort of patients was 24%. The outcomes did not differ significantly between patients who received autologous stem cells and those who received allogeneic stem cells, although patients who underwent allogeneic transplant had a higher rate of complications. A follow-up study from this same group evaluated two consolidation courses of myeloablative melphalan and etoposide in 17 patients with bone metastases.[560] The 5-year event-free survival rate for these patients was 21%.

A later Children's Cancer Group study evaluated melphalan, etoposide, and 12 Gy total-body irradiation for patients with newly diagnosed Ewing sarcoma with bone or bone marrow metastases.[561] These patients received VDC alternating with IE for five cycles along with radiotherapy to their primary tumor and bone metastases. Patients with a complete response or very good partial response to initial therapy received the planned myeloablative therapy. The 2-year event-free survival rate for all 32 patients enrolled in this study was 20%. For the group of patients who were able to receive myeloablative therapy, the 2-year event-free survival rate was 24%. The outcome did not differ from a cohort of historical controls treated in protocol INT-0091. As such, the authors concluded that myeloablative therapy did not improve the outcome for patients with bone and bone marrow metastases.

A French multicenter trial prospectively evaluated the role of high-dose therapy in patients with newly diagnosed metastatic disease.[429] Patients in this trial received initial chemotherapy with cyclophosphamide and doxorubicin alternating with IE. Of the 97 patients enrolled in the study, 75 had a favorable response to initial therapy and proceeded to consolidation therapy with busulfan and melphalan followed by stem cell rescue. The 5-year event-free survival rate was 37% for all 97 patients and 47% for the 75 patients who received high-dose therapy. Much of the improvement after high-dose therapy appeared to be in patients with isolated lung metastases. These patients had a 5-year event-free survival rate of 52% compared with 24% for patients with metastases involving other sites.

A joint Italian and Scandinavian trial treated 102 patients with newly diagnosed metastatic disease, the majority of whom had isolated pulmonary metastatic disease.[562] Patients initially received multiagent chemotherapy and local control measures followed by high-dose chemotherapy with busulfan and melphalan. Patients with lung metastasis at study entry also received 12 to 15 Gy whole lung radiation. High-dose chemotherapy was administered to 79 patients, and the primary reason that the remaining patients did not receive high-dose chemotherapy was early disease progression. The 5-year event-free survival rate for the entire study population was 43%. For patients with isolated pulmonary metastatic disease who were able to receive high-dose chemotherapy and whole lung radiation, the 5-year event-free survival rate was 53%.

A report of 171 patients treated by the EICESS group indicated that high-dose therapy did not improve the outcome among patients with metastatic disease at initial diagnosis.[354] Further analysis suggested that patients with multiple sites of metastases require some form of intensified therapy, either as high-dose therapy or whole lung irradiation. The 4-year event-free survival rate for patients with multiple metastatic sites treated with high-dose therapy, whole lung irradiation, or both modalities was 27% compared with 0% for patients who did not receive at least one form of intensified therapy.[354]

The only randomized study comparing high-dose therapy with other treatment for high-risk patients is ongoing. This trial, known as the EURO-EWING 99 study, randomizes newly diagnosed high-risk patients to receive consolidation therapy with busulfan and melphalan followed by stem cell rescue or continuation chemotherapy. Patients with isolated pulmonary metastases are randomized to consolidation therapy with high-dose chemotherapy and stem cell rescue or to continuation chemotherapy followed by whole lung irradiation. Patients with metastases beyond the lung are nonrandomly assigned to high-dose chemotherapy with stem cell rescue. Of note, patients with nonmetastatic disease with poor response to neoadjuvant chemotherapy are also randomized to high-dose chemotherapy or to continuation chemotherapy. Results of the randomized portion of this trial will not be available for several years. However, patients with extrapulmonary metastatic disease were nonrandomly assigned to receive high-dose chemotherapy and their outcomes have been reported.[563] Of 281 enrolled patients, 169 patients went on to receive high-dose therapy, mainly with busulfan and melphalan conditioning. The event-free survival rate at 3 years for the entire cohort of 281 patients was 27%. The selected group of patients in complete remission at the time of high-dose therapy had a 3-year event-free survival rate of 57%, compared with 32% and 24% for patients with partial response or stable disease/progressive disease, respectively. These results indicate the importance of remission status if high-dose therapy is to be considered in this high-risk patient population.

The use of autologous stem cell infusion raises the concern of re-infusion of Ewing cells contaminating the stem cell product. Several groups have investigated this issue using PCR techniques with mixed results. The incidence of tumor cell contamination ranges from 6% to 100% of pheresis products, depending on the study.[564-567] The largest and most recent evaluation of this issue studied 88 patients with high-risk Ewing sarcoma treated with high-dose therapy with stem cell rescue.[567] Only seven patients had tumor cell contamination of their infused product. The outcome of these seven patients did not appear to differ from the outcome of patients without tumor cell contamination of their infused product.

Summary of Outcomes for Patients with Metastatic Ewing Sarcoma

Despite improved outcomes for patients with nonmetastatic disease over time, patients with initially metastatic disease have not been as fortunate. Most reports suggest that no more than 30% of patients with metastatic Ewing sarcoma are long-term survivors, although this number may be slightly higher for patients with isolated lung metastases.[351,356] Even with combined modality therapy, many patients never attain a complete remission. One recent study reported a complete response rate of only 43% after these patients received chemotherapy, surgery, radiation, and combinations thereof.[548] As such, a number of these patients have treatment-refractory disease. Among patients who do attain a complete remission, disease recurrence remains a major barrier to durable cure.

RECURRENT EWING SARCOMA

Location and Timing of Disease Recurrence

Among patients whose disease recurs, recurrence involving distant sites is more common than isolated local recurrence. Isolated distant relapse accounts for 48% to 71% of recurrences,[568,569] although this appears to be more common in patients with initially metastatic disease.[570-573] Another 10% to 29% of recurrences are combined local plus distant recurrences, and estimates of isolated local recurrence vary widely among studies, ranging from 11% to 35%.[352,570-573] Most initial distant relapses involve the lung, the bones, or both.[571,572]

Most episodes of disease recurrence occur after patients have completed their planned initial therapy. Disease recurrence within 2 years of initial diagnosis is more common than later recurrence, with more than 70% of relapses occurring during this time frame in two large analyses.[568,569] The median time to disease recurrence across several series ranges from 17 to 27 months.[570-573] Patients with initially metastatic disease that recurs have a shorter time to recurrence compared with patients who have initially localized disease that recurs.[569] An analysis of data from the UKCCSG ET-1 and ET-2 studies indicated that patients have a relatively stable rate of death during the first 2 years after diagnosis.[574] Between 2 and 5 years after diagnosis, the rate of death is lower but remains relatively constant during this interval. Only after 5 years from initial diagnosis does the risk of death plateau at an even lower rate that remains constant with extended follow-up. However, Ewing sarcoma can recur very late. In one series 5 of 31 patients who remained disease free for 5 years from the time of initial diagnosis later recurred.[575] In another report 25 of 326 patients who had been in complete remission for 5 years from initial diagnosis experienced late disease recurrence.[576] Other series of patients with recurrent disease include patients with disease recurrence beyond 10 years from initial diagnosis.[570,571,576,577] For example, a report from the Childhood Cancer Survivor Study observed that 26% of late relapses (beyond 5 years from initial diagnosis) occurred 10 or more years from initial relapse.[577] These results highlight the need for extended follow-up in patients with this disease.

General Approach to Patients with Recurrent Ewing Sarcoma

Patients with progressive or recurrent disease after initial therapy present a particular challenge to the clinical team. The time to disease recurrence provides an important indication of the likelihood of long-term survival for these patients (discussed later). More than one quarter of patients with late (more than 2 years from initial diagnosis) recurrence may achieve long-term disease control with aggressive therapy.[568-573] Most clinicians initiate systemic chemotherapy for these patients to assess their sensitivity to the chosen chemotherapy regimen. For patients with chemotherapy-responsive disease, the use of surgery or radiation (or both) for sites of recurrence is often considered. For a local recurrence another attempt at local control may be undertaken with surgery, radiation, or both. For patients with pulmonary recurrence, many clinicians will recommend whole lung irradiation. Patients who respond well to second-line therapy may also be candidates for high-dose therapy with stem cell rescue, although this approach remains unproved (discussed later). Patients with late recurrent disease that does not respond to initial chemotherapy are managed as for poor-risk recurrent disease, according to the strategies outlined in subsequent paragraphs.

For patients with an early (less than 2 years from initial diagnosis) recurrence, the likelihood of long-term disease control is less than 10%.[570-573] Given these data, the appropriate treatment for these patients must be highly individualized, with a clear understanding of the patient's and family's goals for therapy. A variety of strategies are considered for these patients, ranging from palliative measures to aggressive multimodality therapy with curative intent. These patients often receive treatment with the second-line chemotherapy regimens described later in this chapter and are also candidates for investigational phase I and phase II clinical trials. For patients with chemotherapy-responsive disease, more aggressive measures can then be considered.

Systemic Therapies for Recurrent Ewing Sarcoma

Historically, very few chemotherapy options existed for patients with recurrent Ewing sarcoma. As such, patients with late-relapse disease were often treated with agents that they had received at initial diagnosis. In one small series a substantial number of patients who relapsed when they were off therapy responded again to the same agents they received as initial therapy; some of these patients had a durable second remission.[578] Another group reported on 35 patients with disease recurrence after ifosfamide-containing chemotherapy, of whom 34% responded to higher-dose ifosfamide (15 grams/m^2/course).[579] Nevertheless, because of concerns regarding resistance to previously used agents, most clinicians now use newer chemotherapy regimens for patients at the time of relapse. However, for patients who experience late relapses, some clinicians will incorporate previously used active agents into an overall treatment plan that also includes newer second-line regimens. Some of these more common second-line regimens are reviewed here.

Camptothecin-containing regimens have demonstrated efficacy for patients with relapsed Ewing sarcoma. Topotecan monotherapy appears to have limited activity against Ewing sarcoma, with objective response rates of 0% to 10%.[580,581] In contrast, topotecan in combination with cyclophosphamide has a response rate of approximately 30% in patients with relapsed or refractory disease.[582,583] Patients with disease that was refractory to standard alkylator-containing therapy responded to this regimen, which suggests that this response rate was not attributable solely to cyclophosphamide but rather to the combination of topotecan with cyclophosphamide. Patients with newly diagnosed metastatic disease treated in an upfront window study had a response rate of 57% to topotecan and cyclophosphamide.[548] On the basis of this activity, the combination is being evaluated in a COG trial for patients with newly diagnosed localized disease (AEWS1031).

A second camptothecin-containing regimen has shown promise in patients with Ewing sarcoma. An initial phase I study of irinotecan and temozolomide found that this well-tolerated regimen induced one complete response and one partial response among seven patients with Ewing sarcoma treated in this study.[584] A follow-up report that included these seven patients plus seven additional evaluable patients reported an objective response in four patients (28%), although an additional four patients had a mixed response or stable disease.[585] A single-institution series of this same regimen reported a 63% response rate in 19 evaluable patients, confirming the activity of this combination in patients with relapsed disease.[586]

Two carboplatin-based regimens have benefited patients with relapsed or refractory Ewing sarcoma. One group reported a 26% response rate among 39 patients treated with carboplatin, cyclophosphamide, and etoposide.[587] A second group evaluated carboplatin, ifosfamide, and etoposide in patients with a range of relapsed or refractory sarcoma.[588] Of the 21 patients with Ewing sarcoma, 48% had an objective response. The contribution of carboplatin to these responses is unclear because both regimens contain first-line agents that are also effective in the treatment of this disease (ifosfamide, etoposide, and cyclophosphamide).

The combination of docetaxel and gemcitabine has also been tested in patients with recurrent Ewing sarcoma, with limited success. In three retrospective case series that included 11 patients with relapsed disease, only one patient had a partial response to standard doses of this combination.[589-591] A formal phase II study of this same regimen demonstrated a 14% response rate in 14 patients with relapsed disease.[592] One group used higher doses of gemcitabine and docetaxel and observed a 66% response rate, suggesting that if there is activity of this combination, dose intensity may be critical.[593]

A number of novel therapies have been evaluated in patients with recurrent Ewing sarcoma. Of these, the most promising and consistent results have been with monoclonal antibodies targeting the IGF-1R. In initial phase I studies, an early signal of objective responses emerged in a subset of patients with relapsed disease.[594,595] Follow-up phase II studies of several different IGF-1R monoclonal antibodies confirmed this activity, with response rates of approximately 10% to 15% between studies.[596-598] Another study evaluated an IGF-1R monoclonal antibody together with an mTOR inhibitor in 17 patients with Ewing sarcoma and reported tumor regressions greater than 20% in 29% of patients.[599] Follow-up studies are necessary to evaluate these agents in combination with cytotoxic chemotherapy and to identify predictors of response to IGF-1R inhibition.

Role of Surgery and Radiation for Recurrent Ewing Sarcoma

Patients with recurrent Ewing sarcoma typically must respond to systemic therapy for long-term disease control to be possible. However, surgery and radiation also play a role at the time of disease recurrence. One study reported that patients who received surgery for local recurrence had a superior outcome compared with patients who did not receive surgery, although this analysis did not control for the size of the recurrent tumor.[570] This same study reported that whole lung irradiation may benefit patients with isolated pulmonary recurrence.[570] Radiotherapy also plays an important role in controlling pain for patients with refractory Ewing sarcoma.

Pulmonary metastasectomy at relapse has a much more limited role in Ewing sarcoma compared with other diseases, such as osteosarcoma. One group reported that pulmonary metastasectomy did not improve the outcome for patients with Ewing sarcoma and isolated pulmonary relapse.[570] Two groups compared patients who underwent pulmonary metastasectomy and patients with lung metastases that were not resected.[554,600] Both groups suggested that metastasectomy improved the outcome for these patients. However, in both studies patients were selected for resection only in the presence of resectable disease, such that the comparison group may have had a greater burden of disease. Another center described 12 patients with isolated pulmonary relapse treated with surgery alone.[601] Five of these patients remained disease free for at least 3 years. The authors noted that these 12 patients were selected for resection alone on the basis of favorable characteristics, such as a small number of pulmonary nodules and a long period of time from diagnosis to relapse. Whether this strategy would benefit a less favorable group of patients remains to be demonstrated. Currently, pulmonary metastasectomy at relapse is considered mainly for diagnostic purposes and only rarely for therapeutic purposes.

Role of High-Dose Therapy with Hematopoietic Stem Cell Rescue for Recurrent Disease

Some clinicians recommend high-dose therapy as consolidation therapy for patients with recurrent Ewing sarcoma who respond favorably to salvage therapy. Data supporting this approach are relatively limited, particularly because many of the reported studies include both patients with metastatic disease and patients with recurrent disease. Although most studies do not report specific outcomes for patients with recurrent disease, the EICESS group reported that patients treated with high-dose therapy for early relapse had a 5-year event-free survival rate of approximately 45%.[560]

Two reports retrospectively evaluated the impact of high-dose therapy on outcome in patients with recurrent disease. In one series of 64 patients with relapsed disease, seven patients received high-dose therapy with stem cell rescue.[573] The outcomes for these seven patients did not differ from outcomes for patients who received other types of relapse therapy. These results differ from a single-institution report of 55 patients with relapsed Ewing sarcoma, of whom 13 received high-dose therapy with busulfan, melphalan, and thiotepa.[572] Patients who received high-dose therapy had a 5-year progression-free survival rate of 61% compared with 7% for other patients. Because high-dose therapy was offered only to patients who responded to second-line therapy, this report also compared the outcomes of patients who received high-dose therapy and those of patients who had responsive disease but did not receive high-dose therapy. In this analysis high-dose therapy resulted in improved 5-year progression-free survival rate over other therapy (61% versus 21%). A multivariate analysis confirmed that high-dose therapy was an independent predictor of favorable outcome.

Outcomes for Patients with Recurrent Ewing Sarcoma

The outcome for patients with recurrent disease is generally poor. The median overall survival rate from the time of recurrence is 9 to 14 months with current therapies.[568,573] Estimates of 5-year overall survival rates from the time of disease recurrence range from 8% to 23%.[570-573] For patients with recurrent disease, the most widely recognized determinant of outcome is time to disease recurrence. An initial single-institution study noted that four of five patients with relapse more than 5 years from diagnosis were salvaged compared with only 2 of 44 patients with earlier relapses.[575] Follow-up studies have all confirmed this association, including two large cooperative group analyses that both demonstrated that time to relapse was the strongest independent predictor of outcome after first relapse.[568-573] Estimates of 5-year progression-free survival rate for patients with recurrence more than 2 years from initial diagnosis were approximately 30% compared with 7% for earlier relapses.[568,569] Another common finding is that patients with a combined local and distant relapse fare poorly compared with patients who experience either isolated local failure or isolated systemic failure.[568,569] Metastatic site at recurrence has not consistently been associated with outcome after relapse.[568-573]

LATE EFFECTS IN PATIENTS TREATED FOR EWING SARCOMA

Given the nature of the therapy required to treat Ewing sarcoma, patients treated for this disease have an increased risk of developing second cancers. In one large European cohort study, patients with Ewing sarcoma had a thirty-fold increased cumulative risk of developing a solid second cancer 25 years from initial diagnosis.[602] The relative risk that patients will develop a second solid cancer or a bone cancer after Ewing sarcoma was second only to that of patients with an initial primary cancer diagnosis of retinoblastoma.[61,602] In another series survivors of Ewing sarcoma had a risk of second malignancy that was second only to that of survivors of Hodgkin lymphoma.[603] A number of groups have reported that the risk of developing any second cancer continues to increase with increasing time from initial diagnosis of Ewing sarcoma. Estimates of the cumulative incidence of developing any second malignancy from the time of initial diagnosis range from 0.7% to 0.9% at 5 years, 2.9% to 6.5% at 10 years, 4.7% at 15 years, 4.7% to 12.7% at 20 years, and 9% at 25 years.[604-608,609-611] Figure 61-9 demonstrates this trend in one representative report from the Childhood Cancer Survivor Study.[609]

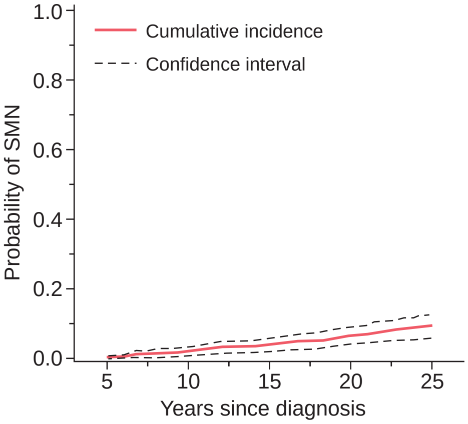

Figure 61-9 Cumulative incidence of second malignancies in patients treated for Ewing sarcoma. *(Ginsberg JP, Goodman P, Leisenring W, et al: Long-term survivors of childhood Ewing sarcoma: report from the childhood cancer survivor study.* J Natl Cancer Inst *102:1272–83, 2010.)*

Radiation-induced sarcomas and chemotherapy-induced acute leukemia constitute the majority of second malignancies seen in these patients. Osteosarcoma accounts for approximately 25% of the secondary sarcomas, with a variety of other bone and soft tissue sarcomas also observed.[604,606,607,612] Estimates of the cumulative incidence of secondary solid cancers are 1.7% to 1.8% in 10-year survivors and 6% to 22% in 20-year survivors.[61,605,606,611,613] This wide range likely results from variations in sample size, follow-up time, and second malignancy surveillance programs between studies. In almost all cases, these secondary sarcomas arise in the initial radiation field. One group has reported that the incidence of these secondary sarcomas increases with increasing radiation dose, with no cases of secondary sarcoma reported in those patients who received less than 48 Gy.[606]

Secondary acute leukemia occurs significantly earlier than secondary sarcomas in these patients.[604,612] Reported mean latency periods from initial diagnosis of Ewing sarcoma to onset of acute leukemia range from 2.3 to 4.8 years, although some patients have developed secondary acute leukemia while still receiving chemotherapy for Ewing sarcoma.[604,612,614,615] Most of these cases of secondary acute leukemia are acute myeloid leukemia or myelodysplastic syndrome. In one large clinical trial, the cumulative incidence of secondary acute myeloid leukemia or myelodysplastic syndrome was approximately 2% 7 years from the initial diagnosis of Ewing sarcoma, with no additional cases observed beyond that time.[614] These cases are characterized by high frequencies of monosomy

5, monosomy 7, and abnormalities at 11q23.[614,615] These cytogenetic findings suggest a role for alkylating agents (cyclophosphamide and ifosfamide associated with monosomy 5 and monosomy 7) and topoisomerase II inhibitors (doxorubicin and etoposide associated with 11q23 abnormalities) in the pathogenesis of these cases. Interestingly, in protocol INT-0091, the incidence of secondary leukemia, including leukemias with the 11q23 abnormality, did not increase with the addition of ifosfamide and etoposide to the regimen of vincristine, doxorubicin, and cyclophosphamide.[614] However, a report from a single institution suggested that the risk of secondary leukemia was increased with more modern treatment protocols that included etoposide.[611] Increased rates of secondary acute myeloid leukemia have been reported in patients with Ewing sarcoma who received augmented doses of alkylating agents and anthracyclines compared with patients who received conventional doses.[614,615] By way of contrast, in protocol INT-0154 increasing the dose rate of alkylating agents while holding the cumulative dose constant did not increase the rate of secondary leukemias.[438]

Patients treated for Ewing sarcoma are at risk for a variety of late effects in addition to second cancers. Cardiac toxicity from anthracycline therapy can result in significant morbidity and mortality rates for these patients. In one small series 6 of 30 Ewing sarcoma survivors developed echocardiographic shortening fractions less than 20% compared with only 1 of 26 patients with soft tissue sarcomas treated with anthracyclines.[616] Both groups of patients received the same mean doxorubicin dose, but patients with Ewing sarcoma received higher individual doses of doxorubicin at shorter intervals. The addition of ifosfamide to chemotherapy regimens for Ewing sarcoma has resulted in the development of chronic renal tubular dysfunction in a subset of these patients.[617] Patients treated with radiation therapy to the bone are at risk for fractures in the radiation field, with an incidence of approximately 20% in one series of Ewing sarcoma survivors.[618] Use of whole lung radiation for patients with lung metastases may result in acute and late pulmonary toxicity, with one series reporting a 7% incidence of severe pulmonary complications.[619] Patients treated for Ewing sarcoma may have hematologic changes after treatment, including mild thrombocytopenia and macrocytosis.[615] Fertility is impaired among survivors of Ewing sarcoma. In one study 29.7% of female survivors reported a pregnancy compared with 40.1% of female sibling controls.[609] The impact of fertility in male survivors may be even greater, with this same series reporting 11.3% of male survivors siring a pregnancy compared with 33.2% of male sibling controls.[609] Indeed, among 23 male survivors of Ewing sarcoma who underwent sperm analysis, 13 were azospermic, 8 were oligospermic, and only 2 were normospermic.[610]

Several studies have evaluated the psychosocial ramifications of treatment for bone sarcomas, including Ewing sarcoma. A study from the Childhood Cancer Survivor Study reported that survivors of lower-extremity bone tumors overall have excellent self-reported orthopedic function and quality of life.[620] Approximately 5% of these patients reported severe or complete disability. Long-term function and quality of life do not appear to differ between patients who underwent amputation and patients who underwent limb-salvage procedures.[620,621] In another report from the Childhood Cancer Survivor Study, survivors of lower-extremity bone tumors were less likely to be married than sibling controls.[622] In addition, adolescents who underwent amputation were less likely to complete high school and were more likely to have difficulties with health insurance issues compared with sibling controls. Some of these findings were replicated in a single-institution study specific to Ewing sarcoma survivors.[623] In this study survivors had lower rates of employment and marriage than sibling controls, although educational attainment and insurance access did not differ between the two groups. All these studies highlight the importance of evaluation for late effects in survivors of Ewing sarcoma.

FUTURE DIRECTIONS

Remarkable gains have been achieved in the treatment of patients with Ewing sarcoma over the past 40 years. During this same period the understanding of the biology of these tumors has also greatly progressed. Future improvements in the management of this disease will require taking advantage of this improved understanding of the events involved in Ewing sarcoma tumorigenesis. Specific avenues of investigation should include therapies directed at key targets in Ewing sarcoma, including IGF-1R, CD99, mTOR, PARP, and EWS/FLI itself. These therapies will likely be attempted first in those patients with the worst prognosis: patients with metastatic disease and patients with early relapse. Effective targeted therapies in these populations will then be applied to patients with lower-risk disease. Targeted therapy holds the promise not only of improving outcomes for patients with Ewing sarcoma but also of reducing exposure to conventional chemotherapy and the late effects of that therapy. For now, further study of the clinical and molecular prognostic features of this disease is required so that current active agents may be applied in a more risk-adapted approach.

CONCLUSION AND FUTURE DIRECTIONS

Osteosarcoma is the most common primary bone tumor. There are approximately 600 cases/year in the United States.[1] The term *osteosarcoma* was first used in the early 1800s by Alexis Boyer,[2] the imperial family surgeon for Napoleon. Although low-grade forms of osteosarcoma do exist, more than 90% of osteosarcomas are high-grade malignant lesions. Low-grade osteosarcomas will be discussed, but most of what follows pertains to high-grade osteosarcomas.

Osteosarcoma usually occurs in adolescents and young adults. Presenting symptoms can include tumor-related pain with or without a mass, a painless mass, and a pathologic fracture. The distal femur is the most frequent site of primary disease, followed by the proximal tibia and then the proximal femur, hip, and proximal humerus.[3] As early as 1818 it was recognized that untreated patients with osteosarcoma often developed metastatic disease.[2] The most common site of metastasis is the lungs, followed by bone. Metastatic disease is present in approximately 15% of patients at the time of diagnosis.[4]

Prior to the 1970s, when chemotherapy was first used to treat osteosarcoma, overall survival (OS) was approximately 20%. With modern chemotherapy and surgical control, the 10-year OS of patients with localized osteosarcoma is around 70%.[5] The OS is much worse for patients with metastases at diagnosis and for those with relapsed disease. In both groups, the 5-year OS rate is approximately 25%.[4,6,7] The most active chemotherapy agents in osteosarcoma are doxorubicin (Doxo), cisplatin (CP), and high-dose methotrexate (HDMTX). Ifosfamide and etoposide are also active against osteosarcoma and are typically used in addition to Doxo, CP, and HDMTX in patients with metastatic disease and in patients with recurrence.

In the past three decades, a number of discoveries have led to a better understanding of osteosarcoma biology. For example, the tumor suppressor gene *TP53* and the retinoblastoma gene *RB1* are altered in osteosarcoma. Oncogenes, including *MYC, MET,* and *FOS,* have also been implicated in osteosarcomagenesis. These tumor suppressors, oncogenes, and other biologic factors will be discussed in detail. Unlike most childhood cancers, there has been minimal improvement in OS over the past three decades.[8,9] Consequently, one of the research priorities in osteosarcoma is the identification of additional active therapies.

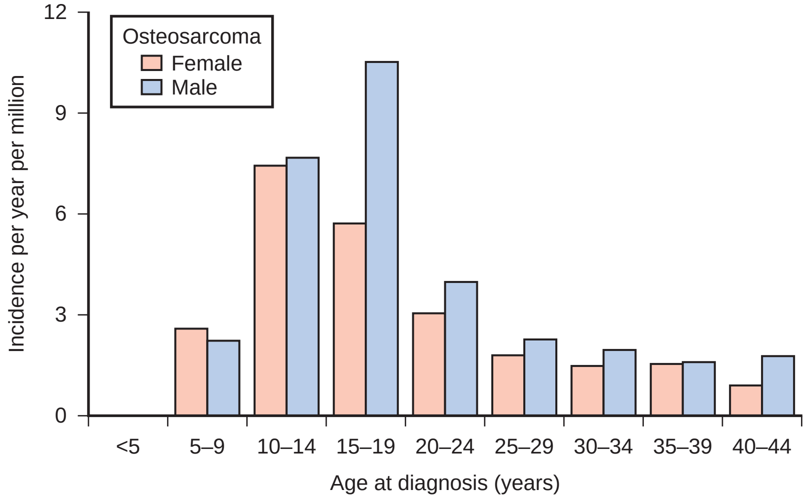

Figure 62-1 Age Distribution of osteosarcoma based on U.S. cases between 1975 and 1999. *(Data from Bleyer A, O'Leary M, Barr R, et al, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000. *NIH publication No. 06-5767. Bethesda, Md., 2006, National Cancer Institute.)*

EPIDEMIOLOGY

Osteosarcoma is the most common primary bone tumor in children.[1] The average annual incidence of osteosarcoma in children younger than 20 years in the United States is 4.8/million. Approximately 3% of all malignancies in this age group are osteosarcomas. In 2000, the most recent year for which data are available, there were 440 cases of osteosarcoma in children from birth to 19 years of age in the United States. There were an additional 135 cases in young adults aged 20 to 29.[1] Internationally, incidence rates approximate the U.S. rate, with the exception of a higher incidence in some African countries. In Sudan and Uganda, the osteosarcoma incidence in children younger than 14 years is 5.3 and 6.4/million respectively, compared with an incidence of between 2 and 3/million in this age group in the United States, Europe, and Asia.[10,11]

Osteosarcoma occurs rarely in children younger than 5 years. After age 5, the incidence increases steadily, reaching a peak at age 15 years.[12] After the adolescent peak, the rate of osteosarcoma steadily declines, leveling off at a rate of 1 to 2/million. A second peak in incidence, approximately half the magnitude of the adolescent peak, occurs in the sixth to seventh decade.[13,14] Osteosarcoma in older patients is associated with Paget disease and prior radiation therapy, although approximately half of older patients with osteosarcoma have neither condition.[15] The adolescent peak occurs at age 13 years in girls and between ages 15 and 17 years in boys (Fig. 62-1). The age at peak incidence corresponds to the age of greatest growth velocity in each gender. This association contributes to the evidence supporting a role for growth in the cause of osteosarcoma (see "Etiology"). Osteosarcoma is slightly more common in males, particularly in the 15- to 19-year-old age group.

In the United States, osteosarcoma is slightly more common in African Americans, Hispanics, and Asians and Pacific Islanders (Fig. 62-2). Several studies have reported that rates of osteosarcoma in black children younger than 14 years are about twice those in white children of the same age.[16,17] In the most recent report on osteosarcoma from the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute, U.S. blacks younger than 20 years continue to have a slightly higher rate of osteosarcoma.[12] As shown in Figure 62-2, for the age group 15 to 29 years, the racial group with the highest rate of osteosarcoma is Hispanic. The relative risk of developing osteosarcoma for Hispanic children younger than 14 years of age, based on data collected between 1975 and 2003, is 1.3.[18] Asians and

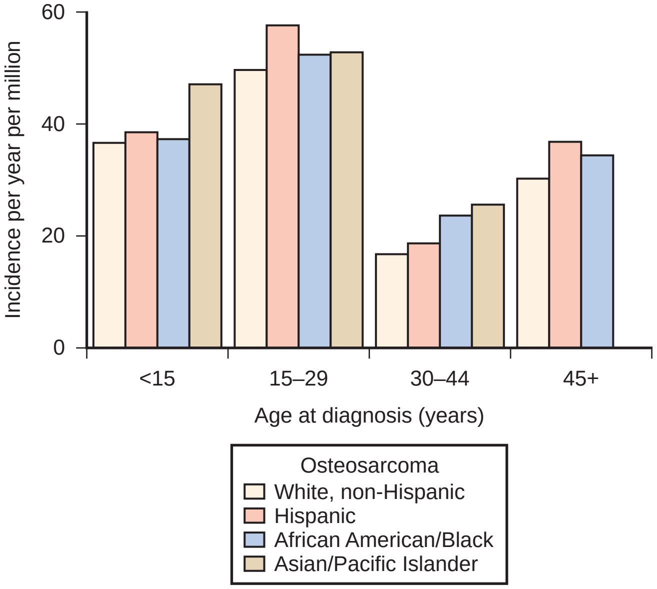

Figure 62-2 Incidence of osteosarcoma by racial group based on U.S. cases between 1990 and 1999. *(Data from Bleyer A, O'Leary M, Barr R, et al, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000. *NIH publication No. 06-5767. Bethesda, Md. 2006, National Cancer Institute.)*

Pacific Islanders have the highest rate of osteosarcoma in the age groups younger than 15 years and 30 to 44 years. However, the reported incidence in Hispanics and in Asians and Pacific Islanders is likely to be inaccurate given the small absolute number of affected individuals and uncertainty in the denominator (i.e., the number of Hispanics and Asians and Pacific Islanders within each age group living in the United States). In summary, there is evidence for a slightly increased incidence of osteosarcoma among U.S. blacks and Hispanics. Recent SEER data show an increased rate in Asians and Pacific Islanders younger than 15 years, but this finding needs further investigation.

The most common anatomic sites of osteosarcoma at initial presentation are the long bones of the lower limbs. Fifty percent of osteosarcomas are located around the knee, in the distal femur, proximal tibia, or proximal fibula (Fig. 62-3). Approximately 10% of tumors occur in the mid or proximal femur, and 9% occur in the proximal humerus.[3,12] Of patients with osteosarcoma, 10% to 20% have metastatic disease at initial presentation. The most common site of metastasis is the lungs. Isolated pulmonary metastases are present in 61% of patients with metastatic disease at presentation. Isolated metastases to bone are present in 16% of patients, and 14% have both pulmonary and bone metastases. Seven percent of patients have metastases to other rare sites plus bone and/or pulmonary metastases, and 2% of patients have isolated metastases to rare sites. Rare sites of metastasis in patients with primary metastatic disease, as opposed to metastatic disease in patients with recurrent disease, are lymph nodes, central nervous system, liver, adrenal gland, and soft tissues.[4]

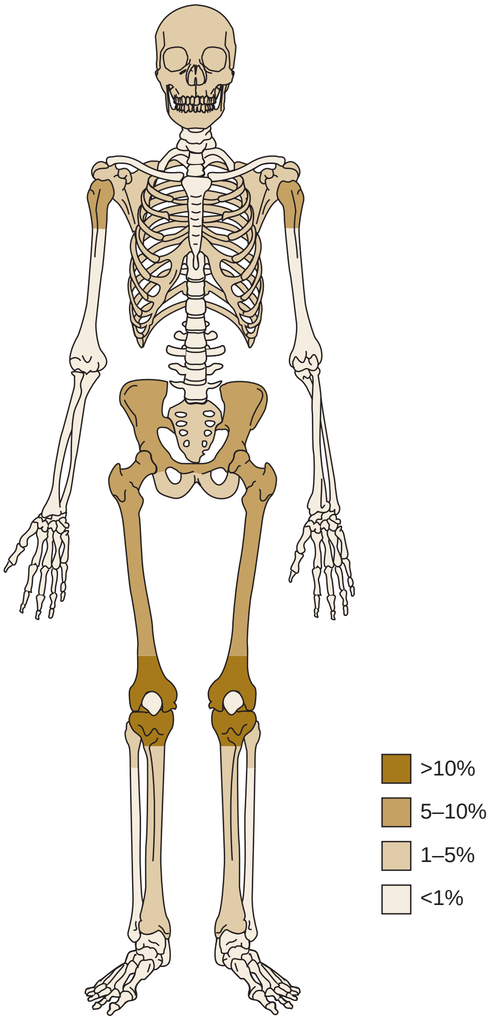

Figure 62-3 Anatomic sites of osteosarcoma at initial presentation. *(Modified from Dahlin DC, Unni KK: Osteosarcoma of bone and its important recognizable varieties.* Am J Surg Pathol *1:61–72, 1977.)*

ETIOLOGY

When a patient presents with osteosarcoma, it is often difficult to identify a cause. However, recognition of causative factors has led to the discovery of biologic mechanisms of transformation, as in the case of predisposition to osteosarcoma in Li-Fraumeni syndrome, or the identification of exposures to be avoided, as in the case of radiation-induced osteosarcoma. Inherited syndromes in which there is an increased occurrence of osteosarcoma are hereditary retinoblastoma and Li-Fraumeni, Rothmund-Thomson, Bloom, and Werner syndromes. There is a clear association between the risk for osteosarcoma and prior radiation therapy or treatment with alkylating chemotherapy. Epidemiologic studies and clinical observation have suggested that increased height may be a risk factor for the development of osteosarcoma. Finally, environmental exposures to radium and beryllium likely increase the risk for osteosarcoma, but exposure to high doses of these agents is rare.

As noted, peak rates of osteosarcoma coincide with the period of maximal linear growth during puberty. Most osteosarcomas occurring in the adolescent age group are in the long bones of the axial skeleton, the bones in which the most active growth occurs. These clinical observations have led to the hypothesis that the hormonal milieu during maximal linear growth encourages the development of osteosarcoma and that, by extension, osteosarcoma would be more common in taller adolescents. Multiple epidemiologic studies have addressed this question,[19-24] but results are contradictory. Approximately 50% of the studies have found that osteosarcoma patients are taller at diagnosis than age-matched controls or the normal population.[22-24] The remaining studies have not supported an association between height and the occurrence of osteosarcoma.[19-21] The larger studies[23] and those with more reliable sources of height data[22] have shown a positive association between tall stature and osteosarcoma. These data, in part, have led to the investigation of the insulin-like growth factor axis in osteosarcoma (see "Biology").

Approximately 1% of patients develop secondary bone tumors after treatment of a primary pediatric malignancy[25]; of these secondary bone tumors, 50% to 80% are osteosarcomas. On the other hand, secondary Ewing sarcoma is rare.[25,26] The relative risk of secondary osteosarcoma increases greatly with radiation doses to the bone higher than 1000 cGy. In patients who received between 3000 and 5000 cGy to the bone during treatment of their primary pediatric malignancy, the relative risk of secondary osteosarcoma was variably reported, but it may be as high as 100.[25,27] A study in patients with primary Ewing sarcoma has concluded that only higher radiation doses increase the risk for secondary sarcomas, with no tumors developing in patients who had received less than 4800 cGy. The highest risk, 130 cases/10,000 person-years of observation, was observed among patients who had received 6000 cGy or more.[28] In the 92 published cases of secondary osteosarcoma for whom radiation dose was reported, the median radiation dose delivered was 4500 to 5400 cGy.[29] The average time between diagnosis of the primary malignancy and development of secondary osteosarcoma is 10 years.[26] Another factor that increases the likelihood that survivors of a primary cancer will develop secondary osteosarcoma is treatment with alkylating agents. This class of chemotherapy increases the relative risk of secondary osteosarcoma by a factor of 5.[25]

Data regarding an increased risk for cancer in people exposed to low levels of radiation from the atomic bombs in Hiroshima and Nagasaki have led to increased concern about the risk of diagnostic imaging with x-rays and computed tomographic (CT) scans, particularly in pediatric patients.[30] However, current evidence does not suggest that osteosarcoma risk would be increased from commonly used imaging modalities.[31] In particular, the radiation dose of a CT scan is approximately 6 cGy and the risk for bone cancer in pediatric cancer survivors who received less than 1000 cGy to the bone is not increased.[25]

Osteosarcoma is seen in a number of inherited cancer predisposition syndromes. These syndromes have often illuminated mechanisms of transformation in sporadic osteosarcoma. Children with hereditary retinoblastoma have a germline heterozygous, inactivating deletion, and/or a frameshift or point mutation of the tumor suppressor gene retinoblastoma 1 *(RB1)*. Affected children develop retinoblastoma usually in one or both eyes. The cumulative incidence of a nonretinoblastoma malignancy in hereditary retinoblastoma is 51%, and approximately 40% of these second malignancies are osteosarcomas.[32] Both osteosarcomas and retinoblastomas in these patients have loss of heterozygosity of the *RB1* allele, resulting in a complete loss of RB1 function. As discussed later (see "Biology"), loss of RB1 function also occurs in sporadic osteosarcomas.[33,34]

In the Li-Fraumeni syndrome, patients carry a heterozygous inactivating mutation of the tumor suppressor gene *TP53*. Affected individuals have a greatly increased cancer risk at a young age. The most common malignancies are breast cancer and bone and soft tissue sarcomas, brain tumors, and leukemia.[35] Slightly more than 10% of the malignancies in patients with Li-Fraumeni syndrome are osteosarcomas. Among patients with Li-Fraumeni syndrome, mutations in the *TP53* DNA-binding domain (as compared with mutations outside the DNA-binding domain or null mutations) are associated with early sarcomas.[36] Patients with osteosarcomas and other cancers that develop in Li-Fraumeni syndrome have loss of the normal *TP53* allele consistent with the tumor suppressor function of the TP53 gene product. Loss of TP53 function by *TP53* mutation or amplification of *MDM2* or *COPS3* is also present in most sporadic osteosarcomas (see "Biology").[37]

Rothmund-Thomson, Bloom, and Werner syndromes are members of a family of autosomal recessive disorders caused by mutations in one of the RECQ DNA helicases. Rothmund-Thomson syndrome, caused by mutations in the *RECQL4* gene, is characterized by rash, skeletal dysplasias, and sparse hair. Up to 30% of patients with Rothmund-Thomson syndrome develop osteosarcoma at a slightly younger age than in sporadic osteosarcoma.[38,39] Bloom syndrome, caused by mutations in the *BLM (RECQL2)* gene, is characterized by short stature, telangiectasia, and an increased risk for developing a wide variety of cancers at a young age.[40] Unlike in Rothmund-Thomson syndrome, only a small percentage of cancers occurring in affected individuals are osteosarcomas. Werner syndrome is caused by a mutation in the *WRN (RECQL3)* gene. Patients have scleroderma-like skin changes, premature aging, and a typical body habitus with short stature, long spindly limbs, and a stocky trunk. Like in Bloom syndrome, the risk for developing cancer at a young age is increased in Werner syndrome. Also like in Bloom syndrome, osteosarcoma constitutes fewer than 10% of the malignancies occurring in patients with Werner syndrome.[41] For a further discussion of the role of RECQ DNA helicases in osteosarcoma, see "Biology".

The risk for developing osteosarcoma is increased in adults with Paget disease. In Paget disease, which affects up to 1% of adults older than the age of 40 years, bone resorption by osteoclasts is increased. As a result, there is a compensatory increase in osteoblast activity and bone formation.[42] Osteosarcoma develops in less than 1% of patients with Paget disease, but this represents a higher rate than that seen in the general population. The average age of patients with Paget disease–related osteosarcoma is 70 years.[15]

A single genome-wide association study has been conducted in osteosarcoma. There are two susceptibility loci achieving statistical significance in osteosarcoma. One locus occurs in a gene desert and the other, at 6p21.3, implicates *GRM4,* a glutamate receptor gene involved in inhibition of the cyclic adenosine monophosphate (AMP) cascade.[43]

Previously, some believed that trauma may cause osteosarcoma. However, modern epidemiologic studies have not supported a relationship between trauma and osteosarcoma.[20] Prior observations linking trauma and osteosarcoma were likely the result of the fact that a traumatic event may result in a previously existing osteosarcoma being brought to medical attention.

Environmental exposures, other than ionizing radiation, for which there is evidence of an association between exposure and osteosarcoma risk, include exposure to radium and beryllium. Radium is a radioactive element that is variably present in well water. When ingested, radium retained in the body is deposited in bone. Studies of those exposed to high levels of radium while painting dials on clocks in the 1920s strongly indicated that exposure to high doses of radium causes osteosarcoma.[44] The risk for osteosarcoma from exposure to low levels of radium in drinking water is less clear. Two studies have shown a slight increase in risk for bone sarcoma or osteosarcoma in those born in areas with drinking water containing relatively high concentrations of radium.[45,46] Conversely, two studies have shown no link between mean levels of radium in water and osteosarcoma.[46,47] Beryllium is a metallic element with limited use in the production of aerospace structural material, x-ray tubes, and nuclear reactors. Although intravenous injection of beryllium salts causes osteosarcoma in rabbits, there is limited evidence of an increased risk for osteosarcoma caused by beryllium exposure in humans.[48] Case-control studies have failed to identify other environmental or occupational exposures that increase the risk for osteosarcoma.[24] Because fluoride can stimulate bone formation there has been concern about a possible relationship between fluoride in drinking water and osteosarcoma. This is a very difficult question to study adequately given that multiple factors beyond water fluoridation may impact fluoride intake. So far, there is no substantial evidence to support a causative association between fluoride exposure and osteosarcoma.[49]

CLINICAL PRESENTATION AND EVALUATION

Clinical, laboratory, and radiologic findings are often highly suggestive of osteosarcoma but are not pathognomonic. Biopsy is always required for diagnosis. Atypical imaging characteristics, including a benign appearance in high-grade osteosarcoma, have been described.[50] The differential diagnosis of osteosarcoma includes benign and malignant bone tumors (Box 62-1; Fig. 62-4).

Osteomyelitis

Clinical Manifestations

Clinical symptoms of osteosarcoma are nonspecific; 25% of patients have pain and a palpable mass at presentation,

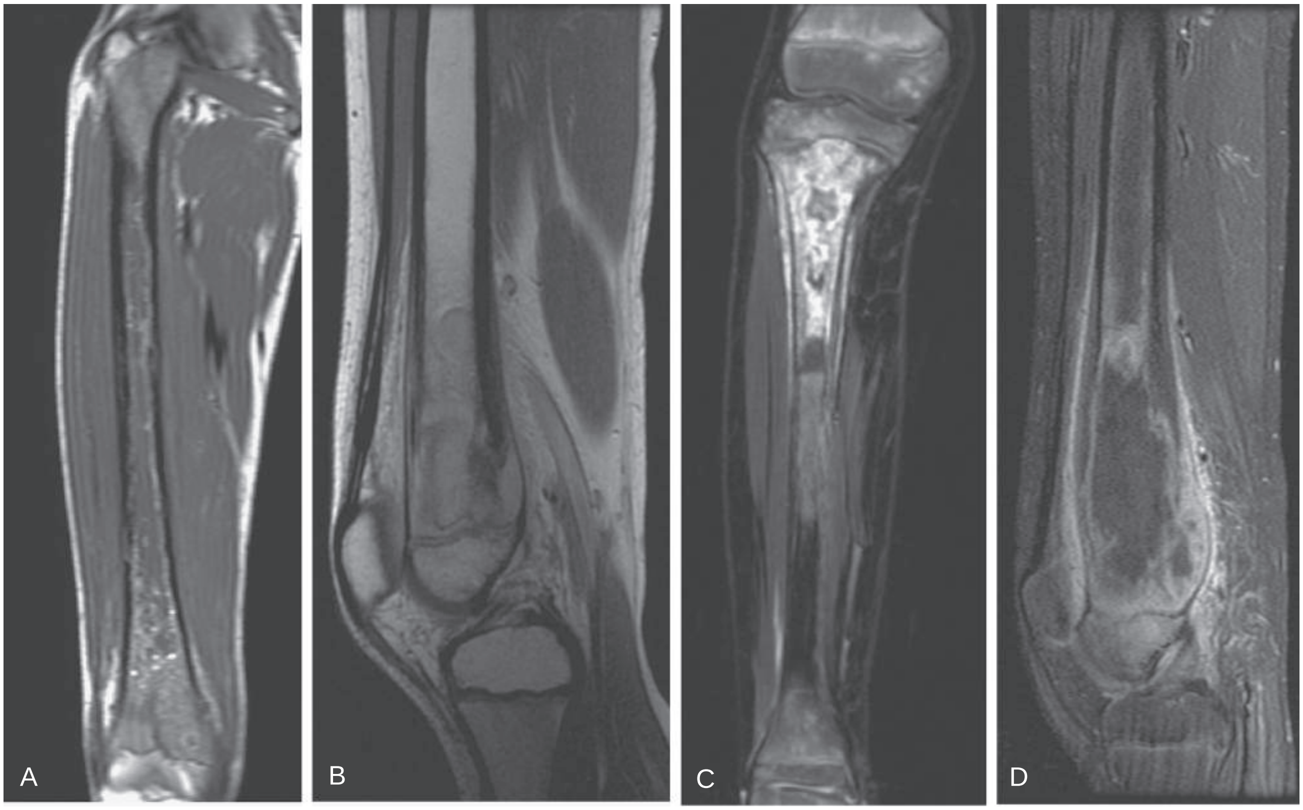

Figure 62-4 MRI appearance of osteosarcoma and lesions that can be confused with osteosarcoma in clinical presentation and radiographic appearance. **A,** Osteomyelitis of the femur. **B,** Lymphoma of the distal femur. **C,** Ewing sarcoma of the proximal tibia. **D,** Osteosarcoma of the distal femur.

and 70% of patients present with pain as their only complaint. Pain tends to be intermittent and exacerbated by activity. The remaining patients present with a painless mass.[51] The duration of symptoms before diagnosis ranges from 1 day to 5 years, with a median of about 2½ months. In approximately 10% of patients, symptom duration is longer than 6 months.[52] A pathologic fracture is present in 8% of patients at the time of diagnosis.[53]

Radiologic Evaluation

Radiologic evaluation in osteosarcoma informs the initial diagnostic impression, aids in the determination of the best approach for biopsy, facilitates surgical resection, and identifies sites of metastatic disease, if present. The recommended imaging studies for osteosarcoma at the time of diagnosis are plain radiography and magnetic resonance imaging (MRI) of the primary tumor site to evaluate the extent of local disease, a bone scan to screen for bony metastases, and a CT scan of the chest to determine whether pulmonary metastases are present. Whenever possible, these imaging studies should be performed before diagnostic biopsy because postsurgical atelectasis interferes with evaluation of the lung parenchyma. MRI of the primary tumor should include the entire bone from which the tumor arises and the closest adjacent joint to screen for skip metastases properly. An additional MR image should be obtained after neoadjuvant chemotherapy has been given but before definitive resection to determine the best plan for the surgical approach.

A plain radiograph of the primary tumor has usually been obtained before referral to an oncologist or orthopedist. Most appendicular osteosarcomas are located in the metaphyseal portion of the long bone. Both lytic destruction of bone and sclerotic irregular new bone formation can occur. Osteosarcoma usually has a mixed pattern of bone lysis and sclerosis, but one of these patterns can predominate. Regardless of the predominant pattern, the boundary between tumor and normal bone is usually irregular. The bone cortex is often disrupted by tumor growth into the surrounding soft tissue. Osteoid formation within the tumor results in areas of calcification visible in the bony and soft tissue components of the tumor. Periosteal new bone formation in osteosarcoma can be irregular or can occur in a sunburst pattern. "Sunburst" refers to linear new bone growth that is perpendicular to the bony cortex and arranged in a fanlike pattern (Fig. 62-5).[54] In contrast, in Ewing sarcoma, periosteal new bone growth typically occurs in an onionskin pattern in which linear new bone is oriented parallel to the bony cortex.[3] Periosteal new bone formation in

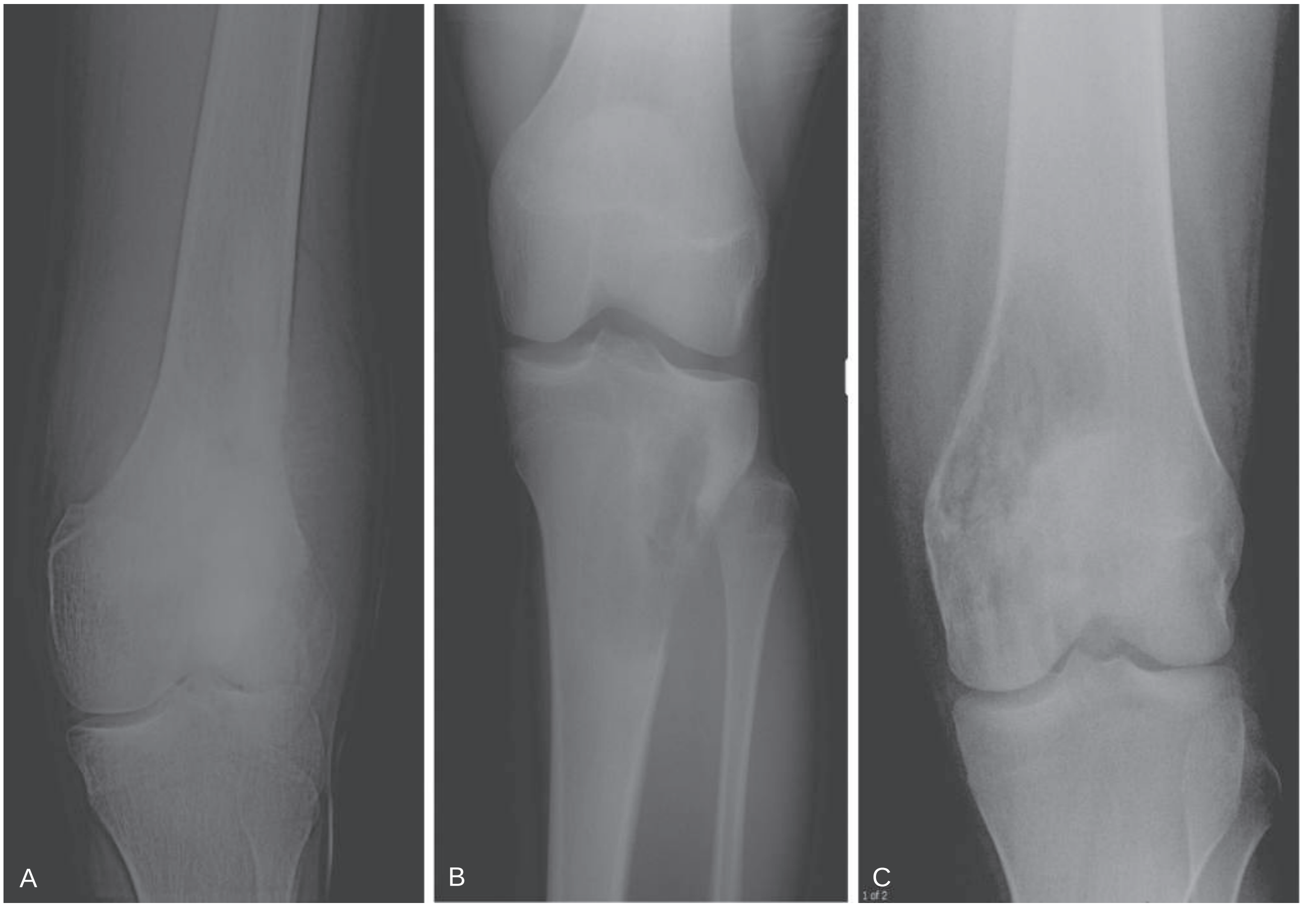

Figure 62-5 Three typical patterns observed in plain radiographs of osteosarcoma. **A,** Predominantly sclerotic pattern in an osteosarcoma of the distal femur with sunburst periosteal new bone formation. **B,** Predominantly lytic pattern in an osteosarcoma of the proximal tibia. **C,** Mixed lytic and sclerotic pattern in an osteosarcoma of the distal femur.

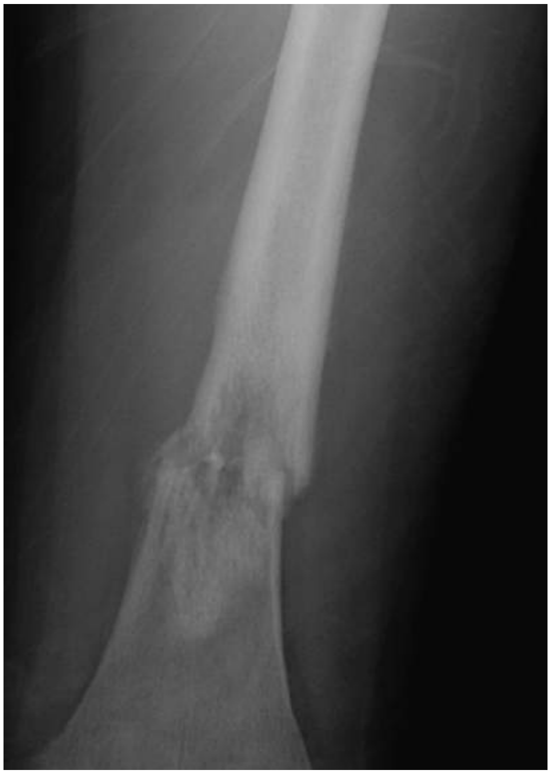

Figure 62-6 Pathologic fracture in an osteosarcoma of the distal femur.

osteosarcoma can also be present at the edge of the preserved cortex, resulting in the Codman triangle. Plain radiographs also assist in the diagnosis of pathologic fractures (Fig. 62-6).

Although plain radiographs of the primary tumor are informative, MRI is preferable for local staging, presurgical planning, and identification of skip metastases. CT is an acceptable alternative to MRI, but most orthopedic surgeons and oncologists prefer MRI. In two studies directly comparing preoperative CT and MRI results with pathologic findings in patients with osteosarcoma, MRI was found to be superior to CT in defining the longitudinal extent of intraosseous tumor,[55,56] extension into adjacent muscle compartments, and involvement of the neurovascular bundle. The two modalities were equivalent in their ability to define cortical bone and joint involvement. However, a more recent study in a larger patient population did not find a statistically significant difference between CT and MRI in their ability to predict the involvement of bone, muscle, joints, and the neurovascular bundle.[57] One possible explanation for the contradictory results is improvements in CT quality during the interval between the studies. In addition, the later study grouped all primary bone tumors together for analysis but, given that 60% of the bone tumors were osteosarcoma, results would likely be similar for osteosarcomas alone. In comparison to CT and technetium-99 m (^{99m}Tc) bone scanning, MRI more accurately predicts the intraosseous extent of osteosarcoma.[56] The presence of significant edema has been associated with inaccurate assessment of the margins of tumor on MRI. Because edema can resolve with chemotherapy, imaging performed for the purpose of surgical planning should be obtained after the administration of neoadjuvant chemotherapy.[58]

A *skip metastasis* is defined as a smaller distinct focus of osteosarcoma that is either within the same bone as the primary tumor or on the other side of the joint adjacent to the primary tumor.[59] There must be normal structures not involved with tumor present between the primary tumor and skip metastasis. Skip metastases are synchronous with the primary tumor and thus are present at initial presentation. Diagnosis of skip metastases is of critical importance for prognostication and because complete surgical remission in osteosarcoma with skip metastases requires complete resection of both the primary tumor and skip metastases. Over 80% of skip metastases are visible on MR images (Fig. 62-7). In contrast, skip metastases are visible on bone scan, CT scans, and plain radiographs in only 46%, 45%, and 36% of cases, respectively.[60] Interestingly, a common reason for failure to identify skip metastases by bone scanning is merging of the signal from the primary tumor with the signal from the skip metastasis.[61] To ensure that skip metastases are identified, MRI of the primary tumor should include the entire bone and adjacent joint. Bony metastases that are not skip metastases are best identified with a ^{99m}Tc bone scan (Fig. 62-8).[61] The usefulness of ^{18}F-labeled fluorodeoxyglucose positron emission tomography (FDG-PET) in osteosarcoma has not yet been adequately evaluated. Results of preliminary studies have suggested that FDG-PET is more useful for assessing tumor response to chemotherapy and for posttherapeutic

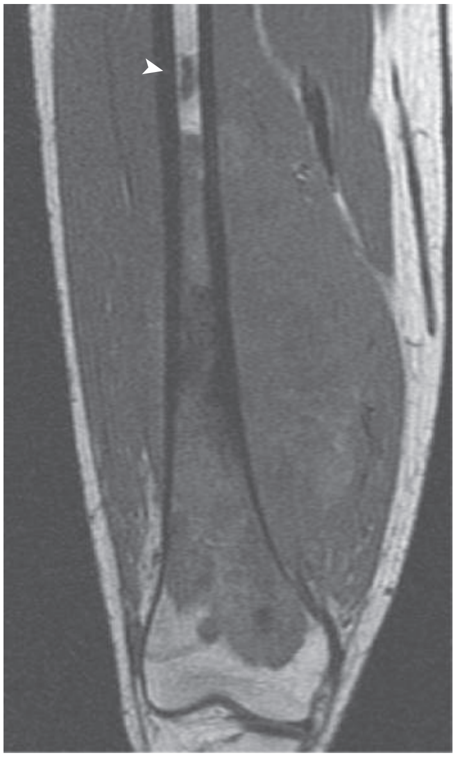

Figure 62-7 Skip metastasis *(arrowhead)* of an osteosarcoma of the distal femur as seen on T1-weighted MR image.

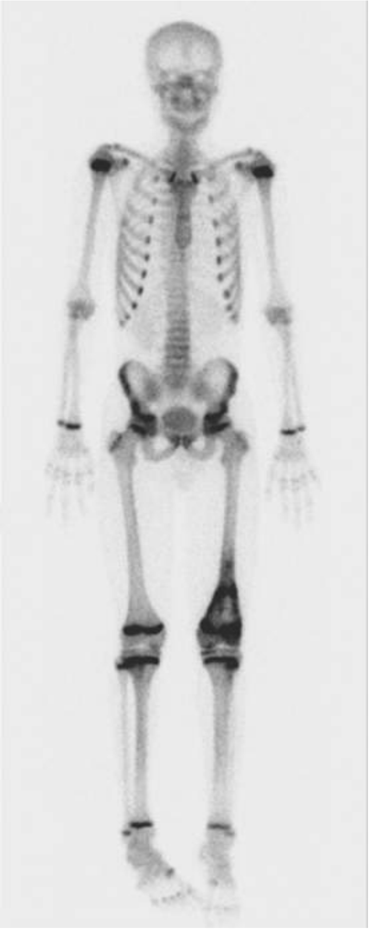

Figure 62-8 Technetium-99 m bone scan showing an osteosarcoma of the distal femur without distant bony metastases.

monitoring for recurrence than for assessing the initial tumor.[62] Because edema can resolve with chemotherapy, imaging performed for the purpose of surgical planning should be performed after the administration of neoadjuvant chemotherapy.[58]

CT of the chest is the most sensitive radiologic study for detection of pulmonary metastases. A generally accepted definition of definitive pulmonary metastatic disease is three or more lesions 5 mm or larger or one lesion 1 cm or larger.[63] The interpretation of very small lesions (<5 mm) and solitary lesions between 5 mm and 1 cm detected by high-resolution CT can be difficult. In some cases, it is not possible to determine whether such CT findings represent metastatic disease or a nonmalignant lung process, and biopsy may be needed. Compared with a CT scan, a plain radiograph of the chest has a sensitivity of 57% and a ^{99m}Tc bone scan has a sensitivity of 41%.[64] Although CT is highly sensitive, evaluation at the time of thoracotomy usually reveals more pulmonary metastases than are appreciated on the CT scan.[65] Importantly, chest CT scans should be obtained before biopsy of the primary tumor because postanesthesia atelectasis makes chest CT scans more difficult to interpret.

Whole-body MRI screening as a method of surveillance in patients with cancer predisposition is currently being evaluated. In a small group or individuals (n = 25) with hereditary retinoblastoma, whole-body MRI detected two cases of osteosarcoma. An additional individual was diagnosed with osteosarcoma due to symptoms.[66] A screening protocol including whole-body MRI utilized in individuals with Li-Fraumeni syndrome detected no cases of osteosarcoma but did detect one case of malignant fibrous histiocytoma.[67]

Biopsy

Traditionally, bone tumor tissue for pathologic examination was obtained by open biopsy. However, percutaneous core needle biopsies have become more common as the availability and sophistication of interventional radiology services have increased. A number of retrospective series have reported on the diagnostic yield and accuracy of core needle biopsies in osteosarcoma.[68-73] Although none specifically studies pediatric osteosarcoma, all series that provide patient age included children. In these published series, core needle biopsy resulted in a definitive, correct diagnosis in 78% to 94% of cases. The more recently published series have reported a diagnostic accuracy of 90% or greater.[69,73] However, even those percutaneous biopsies that yield sufficient tumor material for a diagnosis often do not yield sufficient tumor specimen for other biologic studies.

The outcome of percutaneous biopsy varies depending on the provider, technique, and patient population. In the published series reporting a high diagnostic yield, biopsies were performed by experienced interventional radiologists in consultation with orthopedic surgeons in tertiary or referral centers with considerable expertise in the diagnosis and management of bone tumors. In the more recent series, patients underwent conscious sedation or were given general anesthesia. Specific techniques included the use of fluoroscopic, CT, or ultrasound guidance and use of at least a 14-gauge needle. The tumor component targeted for biopsy was the soft tissue mass, if present, followed by the lytic aspect of an intraosseous lesion.

The most common reason for failure to obtain diagnostic tissue by core needle biopsy is the presence of a highly sclerotic tumor.[70,71] Of the various types of osteosarcoma, telangiectatic osteosarcoma most often results in a nondiagnostic specimen or is misdiagnosed.[69,70] Development of osteosarcoma in a percutaneous biopsy tract has been reported.[74] Therefore, it is important that the biopsy site be located so that it can be resected en bloc with the primary tumor. Because fine-needle aspiration has a diagnostic yield lower than core needle biopsy[68] and does not obviate the need for sedation in the pediatric population, it is not a recommended approach for diagnosis.

Surgical or open biopsy of bone tumors can be incisional or excisional. Excisional biopsy is almost never performed in osteosarcoma because neoadjuvant chemotherapy can decrease tumor edema and, in doing so, simplify resection. In addition, time is required for adequate surgical planning, especially for younger children in whom placement of a growing prosthesis is being considered. Complications of open biopsy include anesthesia-related events, infection, bleeding, and tumor seeding in the biopsy tract.[75] In addition, disruption of anatomic compartments and incorrect localization of the biopsy incision can lead to a more complex or more extensive tumor resection and can occasionally result in an amputation that would not have otherwise been necessary.[76] As with percutaneous biopsy, the incision for an open biopsy should be placed and oriented in a way that allows it to be excised en bloc with the primary tumor. Complications of open biopsy, including those that result in more extensive resections, are unusual when the biopsy is performed at a center specializing in the diagnosis and treatment of malignant bone tumors.[77]

In summary, the percutaneous and open biopsy routes are both acceptable. Given the implications for ultimate surgical resection of a poorly performed biopsy, biopsy should be performed or planned by an orthopedic surgeon with bone tumor expertise, ideally by the same orthopedic surgeon who will perform the ultimate resection. Percutaneous biopsies should only be performed by experienced interventional radiology staff working in conjunction with an experienced orthopedic surgeon. If the percutaneous route is recommended, it is important to counsel patients and families about the possible risks of core needle biopsy, including the potential for an inconclusive specimen. For a further discussion of the debate regarding the correct route for bone tumor biopsy, see Box 62-2.

Laboratory Evaluation

Laboratory test results are often normal in osteosarcoma. When laboratory abnormalities are present, they are nonspecific, having many other potential causes. The serum alkaline phosphatase level is elevated in approximately 50% of patients presenting with osteosarcoma.[78,79] A higher percentage of patients with metastatic disease have a high alkaline phosphatase level, but this is not a reliable test of metastatic disease, because some patients with metastatic disease will have a normal result. As will be discussed later, alkaline phosphatase elevations are associated with a poorer prognosis. Lactate dehydrogenase (LDH) is elevated in approximately 30% of osteosarcoma patients.[80] The erythrocyte sedimentation rate is generally not elevated in patients with osteosarcoma, whereas it is often elevated in those with Ewing sarcoma.

PATHOLOGY AND STAGING

Pathology

On gross examination, osteosarcoma usually presents as a large mass located in the metaphysis (Fig. 62-9) arising in the medullary cavity and crossing the bony cortex, with invasion into the adjacent soft tissues. Microscopically, the malignant cells are pleomorphic but spindle cells typically predominate. Epithelioid, small round cells, multinucleated giant cells, and plasmacytoid cells may also be present and occasionally are the predominant morphology.[81] Osteoid, which can be plentiful or sparse, is currently essential for the diagnosis of osteosarcoma. Sometimes, it is not present in the initial biopsy sample but is seen in the definitive resection specimen. If not

Box 62-2 **Controversies in Osteosarcoma: Open vs. Core Needle Biopsy**

There are two possible approaches to obtaining a diagnostic specimen in suspected osteosarcoma—open biopsy and core needle biopsy. Considerable controversy exists regarding which diagnostic approach is best. An open biopsy is performed in the operating room by an orthopedic surgeon. As discussed in more detail in the text, an open biopsy should be performed by orthopedic surgeon with experience treating bone tumors and ideally by the same orthopedic surgeon who will ultimately perform the tumor resection. In a core needle biopsy, while imaging the tumor with CT, an interventional radiologist obtains several needle cores of tumor material. As with an open biopsy, a core needle biopsy should be performed by an interventional radiologist with expertise in the diagnostic evaluation of bone tumors. Planning for core needle biopsy should include a discussion with the orthopedic surgeon who will ultimately perform the resection. The relative merits of core needle and open biopsy as they relate to several core issues are discussed below:

1. DEFINITIVE DIAGNOSIS

Because orthopedic surgeons directly visualize a tumor during an open biopsy and because pathologists often view frozen sections during open biopsies, nondiagnostic open biopsies are uncommon. In retrospective series,[68-73] core needle biopsy results in a definitive, correct diagnosis in 78% to 94% of cases. The more recently published series report a diagnostic accuracy of 90% or more.[69,73] The interventional radiology-guided core needle biopsies in these studies were performed in centers with considerable experience with the diagnosis of bone tumors and similar diagnostic accuracy would not be expected in inexperienced centers. Less tumor material is obtained from core needle biopsies, which can compromise the pathologist's ability to perform additional testing, such as cytogenetics, in some cases.

2. POSTPROCEDURE RECOVERY

Both core needle and open biopsies require general anesthesia in children. In general, open biopsies are longer procedures, requiring a greater length of general anesthesia. Open biopsies are also more invasive and result in a longer postprocedure recovery.

3. IMPACT ON ULTIMATE RESECTION

Whether the biopsy approach is core needle or open, definitive surgical treatment of osteosarcoma, which is essential for cure, requires excision of the biopsy tract or site en bloc with the primary tumor. A poorly placed biopsy can convert a tumor amenable to limb-sparing surgery into one that requires amputation. This impact on ultimate resectability is one of the greatest potential negative aspects of core needle biopsy. Because interventional radiologists are less knowledgeable about surgical approaches for definitive tumor resection in osteosarcoma, the risk of a poorly placed biopsy is potentially higher with a core needle biopsy. However, supporters of core needle biopsy argue that this risk can be reduced through discussion of the biopsy with the patient's treating orthopedic surgeon.

4. IMPACT ON BIOLOGIC STUDIES OF OSTEOSARCOMA

Although the availability of tumor material for the study of osteosarcoma biology is not an important issue from the perspective of the individual patient with osteosarcoma, it is an important issue from the perspective of researchers and future patients who could benefit from research discoveries. Because tumor resection occurs after the administration of chemotherapy, osteosarcoma resection specimens are often not suitable for laboratory investigation. After open biopsy there is usually sufficient prechemotherapy tumor material available for biologic studies after the diagnosis is made. This is not the case with core needle biopsies. Thus, progress in osteosarcoma research would likely be negatively affected if the majority of centers were to perform core needle biopsies.

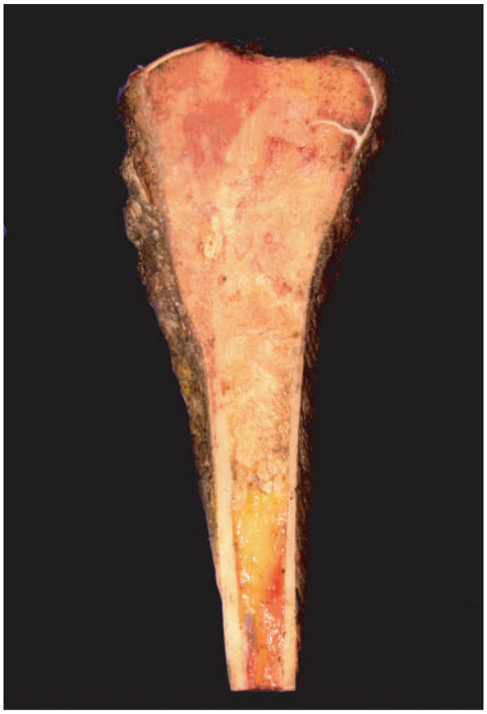

Figure 62-9 Osteosarcoma: gross pathologic appearance.

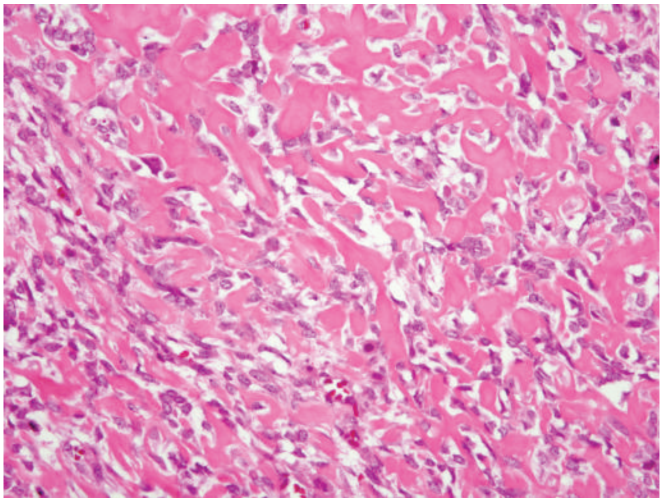

Figure 62-10 High-grade osteosarcoma composed of malignant-appearing tumor cells having a high nuclear-to-cytoplasmic ratio, hyperchromatism, and prominent nucleoli and an abundant eosinophilic osteoid matrix.

present in either, the diagnosis of osteosarcoma cannot be made with certainty. The histologic appearance of osteoid is dense, pink, and amorphous. Classic or conventional osteosarcoma comprises 70% to 80% of cases of osteosarcoma.[79] A number of other types of osteosarcoma are distinguished from classic osteosarcoma based on clinical or pathologic features (Table 62-1).

Classic osteosarcoma has a highly malignant appearance, with prominent anaplasia and frequent mitoses. There is variability in the histologic appearance of conventional osteosarcoma. To facilitate pathologic diagnosis and best describe this variability in appearance, classic osteosarcoma is divided into three subtypes based on the predominant matrix produced by the malignant cells.[79] In the first, 50% of typical osteosarcoma is osteoblastic osteosarcoma, in which osteoid is the predominant matrix (Fig. 62-10). Next, 25% of typical osteosarcoma is chondroblastic osteosarcoma in which cartilaginous islands are the predominant matrix. This subtype is differentiated from chondrosarcoma by the presence of osteoid. Because osteoid can be sparse in chondroblastic osteosarcoma, distinguishing chondroblastic osteosarcoma from chondrosarcoma can require extensive biopsy material, which may necessitate rebiopsy. Sixty-one percent of chondrosarcomas have mutations in the isocitrate dehydrogenase 1 and 2 genes (*IDH1* and *IDH2*). Mutations in these genes have not been seen in osteosarcoma. Therefore, the identification of an *IDH1* or *IDH2* mutation in a malignant bone tumor with a chondroid matrix would strongly suggest a diagnosis of chondrosarcoma.[82,83] The remaining 25% of typical osteosarcoma is fibroblastic. In fibroblastic osteosarcoma, osteoid is minimal and spindle cells grow in a herringbone pattern.[3]

TABLE 62-1 Pathologic Features and Relative Frequency of Osteosarcoma Subtypes

Type	Pathology	Approximate % (of all Osteosarcoma)
Classic	Anaplastic, numerous mitoses	70-80
Osteoblastic	Predominant matrix osteoid	35
Chondroblastic	Predominant matrix chondroid	18
Fibroblastic	Spindle cells in herringbone pattern	18
Jaw	Similar to classic osteosarcoma	3-7
Secondary	Similar to classic osteosarcoma	7
Telangiectatic	Cysts and septa, scant osteoid, giant cells present	4-10
Small cell	Small round malignant cells, osteoid present but quantity variable	1-4
Low-grade intramedullary	Minimal atypia, few mitoses	1-2
Parosteal	Located on bone surface, low grade, matrix osteoid and, in 50%, cartilage	4
Periosteal	Located on bone surface, intermediate grade, predominant matrix cartilage	1-2

Many osteosarcomas have a mixture of different histologies, but in mixed histology cases one histology usually predominates. Of note, the subtypes of typical osteosarcoma were originally designated for the purpose of diagnosis, and their prognostic significance is uncertain. A better histologic response to chemotherapy in fibroblastic osteosarcoma and a poorer histologic response to chemotherapy in chondroblastic osteosarcoma have been consistent findings in several studies.[80,84,85] Telangiectatic osteosarcoma also has a better histologic response to chemotherapy (see later). Whether these differences in histologic response to therapy are correlated with differences in OS is not entirely clear. In the largest study to evaluate this question, there was a slight, statistically significant 5-year OS advantage in patients with fibroblastic osteosarcoma. Unlike other types of osteosarcoma, histologic response to chemotherapy may not be correlated with outcome in chondroblastic osteosarcoma.[85]

The remaining 20% to 30% of osteosarcomas that are not classic osteosarcomas are divided into secondary (occurring in Paget disease or after irradiation), jaw, telangiectatic, small cell, parosteal, periosteal, and low-grade intramedullary osteosarcoma. Telangiectatic osteosarcoma accounts for 4% to 11% of all osteosarcoma cases.[79,86-88] The age and gender distribution are the same as in conventional osteosarcoma. Pathologic fracture is more common, occurring in 15% to 25% of cases.[79,87,88] Radiographically, a lytic pattern is present because of the presence of large or small cystic areas and minimal osteoid formation. Microscopically, cysts are divided by septa that are lined with malignant cells producing scant osteoid. Cysts are also lined by benign, multinucleated giant cells. The presence of cysts and multinucleated giant cells can lead to misdiagnosis as an aneurysmal bone cyst or giant cell tumor, both benign bone tumors.[79] Although case series published prior to the modern era of multiagent chemotherapy had reported that telangiectatic osteosarcoma has an adverse prognostic implication, more recent studies have reported a better histologic response to therapy and improved survival as compared with typical osteosarcoma.[85-87]

Small cell osteosarcoma is a rare but histologically distinct variant representing 1% to 4% of osteosarcomas.[89,90] The clinical and epidemiologic characteristics are the same as conventional osteosarcoma. Microscopically, tumors are composed of small round cells that produce variable amounts of osteoid. Differentiation from Ewing sarcoma and lymphoma can be difficult.

Osteosarcomas of the jaw, located in the maxilla or mandible, deserve specific mention. Even when secondary osteosarcomas are excluded, the mean age of patients with osteosarcoma in this location is the mid-30s, which is older than in classic osteosarcoma.[79,91,92] These tumors are more often low grade; approximately 50% are low grade in most series.[92,93] Histologically, the appearance is similar to that of classic osteosarcoma but a larger proportion of tumors are chondroblastic. In concordance with the greater proportion of low-grade tumors, prognosis is better for osteosarcoma of the jaw. Although local recurrence does occur, especially when the initial resection is inadequate, metastasis is unusual.

Low-grade intramedullary osteosarcoma is relatively rare, making up 1% to 2% of all osteosarcomas. Patients developing this form of osteosarcoma tend to be older than those with conventional osteosarcoma, with 30 years being the mean age at diagnosis. Microscopic examination reveals spindle cells permeating bony trabeculae, with minimal atypia and few mitoses. A variable amount of osteoid is present. Recurrence and metastasis are rare. With adequate resection, chemotherapy is generally not indicated.[94,95]

Parosteal osteosarcoma is another low-grade osteosarcoma distinguished from low-grade intramedullary osteosarcoma by its location on the cortical surface of the bone. It is generally a sclerotic tumor attached to the bone by a broad base. Microscopically, the stroma is sparsely populated by minimally atypical spindle cells. The matrix contains osteoid and, in 50% of cases, cartilage.[96] A limited degree of medullary involvement is seen in 25% of cases. Areas of dedifferentiation can be present at diagnosis or at the time of recurrence and portend a poorer prognosis. Of patients with dedifferentiation, 31% will die of disease, usually with pulmonary metastasis.[97] Parosteal osteosarcoma makes up approximately 4% of all osteosarcomas. Like intramedullary low-grade osteosarcoma, parosteal osteosarcoma occurs in slightly older patients than conventional osteosarcoma and recurrence and metastasis are rare in adequately resected cases without dedifferentiation.[98]

Parosteal osteosarcoma must be distinguished from periosteal osteosarcoma. Periosteal osteosarcoma also arises from the surface of the bone but is an intermediate- or high-grade lesion. Periosteal osteosarcoma has an age distribution similar to that of typical osteosarcoma but almost all tumors arise in the proximal tibia. The appearance on plain radiography is highly characteristic and suggests the diagnosis. Histology is of a spindle cell neoplasm with osteoid and cartilaginous islands present, usually in large amounts. The prognosis is better than in conventional osteosarcoma but probably not as good as in parosteal osteosarcoma without dedifferentiation or intermedullary low-grade osteosarcoma.[99] There is controversy regarding the need for chemotherapy for periosteal osteosarcoma. The entity is too rare to permit conduct of prospective randomized controlled trials. Interpretation of retrospective series is difficult because variability in chemotherapy administration likely correlates with variability in clinicopathologic features related to outcome.[100,101]

Secondary osteosarcoma arises in previously irradiated bone or in patients with Paget disease. In both cases, patients are older than those with conventional osteosarcoma. Pathology is similar to conventional osteosarcoma. Prognosis is poorer in Paget disease than in conventional osteosarcoma.[84] There is some evidence that radiation-induced osteosarcomas have similar outcomes to de novo osteosarcoma if standard osteosarcoma chemotherapy is given.[102,103]

Staging

Staging of osteosarcoma follows the Enneking[104] or musculoskeletal society staging system (Table 62-2). The

TABLE 62-2 Enneking Staging System for Osteosarcoma: Distribution of Osteosarcoma and Indicated Treatment by Stage

Stage	Grade	Site	Metastasis	% of Patients[107]	Surgical Margin	Chemotherapy	Representative Subtype
IA	G1	T1	M0	5	Wide	No	Parosteal
IB	G1	T2	M0	3	Wide	No	
IIA	G2	T1	M0	5	Wide	Yes	Periosteal
IIB	G2	T2	M0	74	Wide	Yes	Classic
III	G1, G2	T1, T2	M1	13	Variable	Yes	Classic

Modified from Enneking WF, Spanier SS, Goodman MA: A system for the surgical staging of musculoskeletal sarcoma. Clin Orthop Relat Res *(153):106–120, 1980.*

G1, Low grade, characterized by few mitoses and a relatively well-differentiated appearance; *G2,* high grade characterized by higher mitotic rate and a less differentiated appearance; *M0,* no distant metastases present; *M1,* distant metastases present; *T1,* tumor is intracompartmental or confined to the anatomic compartment of origin; *T2,* tumor is extracompartmental or extends beyond the anatomic compartment of origin.

TNM system is not used for several reasons. The TNM system lacks biologic relevance in that osteosarcoma seldom metastasizes to lymph nodes. In addition, it is more complex than needed for predicting outcome, because patients in different TNM stages have overlapping prognoses.[104]

The Enneking staging system is based on tumor grade (G), site (T), and metastases (M). Low-grade (G1) tumors are well differentiated and have few mitoses, corresponding to Broders grades I and II.[95] Osteosarcoma is high grade (G2) if it is poorly differentiated and has numerous mitoses, corresponding to Broders grades III and IV. As noted, most osteosarcomas are high grade (G2). Surgical site (T) is determined by whether the tumor is contained within its anatomic compartment of origin (T1) or extends beyond its compartment of origin (T2). For example, a typical osteosarcoma that arises in the medullary space and extends through the cortex into the soft tissue is T2. A parosteal osteosarcoma that does not extend from the bone surface, its site of origin, into the medullary space and does not invade the surrounding soft tissue is T1. Most classic osteosarcomas are T2. Metastases are absent (M1) or present (M2). Stages IA and IB are low-grade (G1) tumors. Stages IIA and IIB are high-grade tumors. Stage IA tumors are low-grade osteosarcomas that are T1 or lack extension beyond the compartment of origin. Stage IB tumors are low-grade osteosarcomas that are T2 or demonstrate extension beyond the compartment of origin. Similarly, stage IIA tumors do not have extracompartmental extension, whereas IIB tumors do. Stage III osteosarcomas are tumors of any grade and any site that have distant metastases.[104-106] The vast majority of osteosarcomas are stage IIB. The next most common stage for osteosarcoma at presentation is stage III. Stages IA, IB, and IIA are uncommon, with 3% to 5% of osteosarcomas falling into each of these categories.[107]

NATURAL HISTORY AND PROGNOSIS

The most significant predictor of survival in osteosarcoma is the presence of residual disease caused by incomplete resection of primary tumor in localized osteosarcoma, local recurrence, or the presence of metastases. Consequently, the natural history, prognosis, and prognostic factors of localized, relapsed, and metastatic osteosarcoma differ significantly.

Localized Disease

Natural History

Prior to the use of chemotherapy for osteosarcoma, the OS of patients with localized disease who had a complete resection was 20%. Death was almost always caused by complications of pulmonary metastases.[79,108] With wide or radical surgical margins, local recurrence was rare. The development of pulmonary metastases in 80% of patients treated with only complete resection of the primary tumor has been interpreted as evidence of the presence of micrometastatic foci in the lungs at the time of diagnosis[109] and was one rationale for adjuvant chemotherapy.

Five-year event-free survival (EFS) and OS of localized osteosarcoma in the era of modern therapy are 65% to 75% and 70% to 80%, respectively.[110,111-113] Approximately 80% of relapses are pulmonary either alone or, in 25% of patients, with a second disease site, which is most often bone. Bone, distant from the initial resection, is the initial relapse site in 8% of patients; 1% to 2% of patients have recurrence isolated to unusual sites such as brain, kidneys, heart, or liver.[6,7,114] Local recurrence is seen in 2% to 8% of patients, despite having had adequate surgical margins.[53,115,116] Most relapses occur during the first 2 years after completion of chemotherapy. However, relapses occur as late as 10 years and the EFS decreases slowly between 2 and 10 years. In the few studies reporting long-term follow-up data, EFS decreases to 60% at 10 years from 65% at 5 years.[115,117]

Prognostic Factors

The most consistent predictor of outcome in localized, fully resected osteosarcoma is the extent of tumor necrosis after neoadjuvant chemotherapy.[52,53,118-121] When investigators at the Memorial Sloan-Kettering Cancer

TABLE 62-3 Grading of Histologic Response to Neoadjuvant Chemotherapy

Response	Grade	Histology
Poor	I	Necrosis minimal or absent
	II	Necrosis is <90% of the tumor but greater than minimal
Good	III	Scattered areas of viable tumor but >90% of tumor necrotic
	IV	No viable tumor

Modified from Rosen G, Caparros B, Huvos AG, et al: Preoperative chemotherapy for osteogenic sarcoma: selection of postoperative adjuvant chemotherapy based on the response of the primary tumor to preoperative chemotherapy. Cancer *49:1221–1230, 1982.*

Center first gave neoadjuvant, or preoperative, chemotherapy to facilitate surgical resection without amputation, they noted varying degrees of necrosis on pathologic examination of resected tumor specimens.[122] It was later observed that patients with significant necrosis had a better EFS and OS than those with lesser degrees of necrosis.[123] However, tumor response is not a true prognostic factor because it cannot be determined until after the initiation of chemotherapy.

The generally accepted grading system for tumor necrosis (Table 62-3) assigns higher grades to tumors with greater evidence of necrosis. In most studies, grades III and IV, in which more than 90% of the tumor is necrotic, define the group of patients whose tumors have a good response to chemotherapy. Patients whose tumors have a poor response have 10% or more viable tumor, corresponding to grades I and II. Patients with a poor response have disease-free survival (DFS) rates of 40% to 50%, whereas those with a good response have DFS rates of 70% to 80% (Fig. 62-11).[111,124-126] An improved outcome for poor responders is an objective of past and current trials (see "Chemotherapy for Localized Disease").

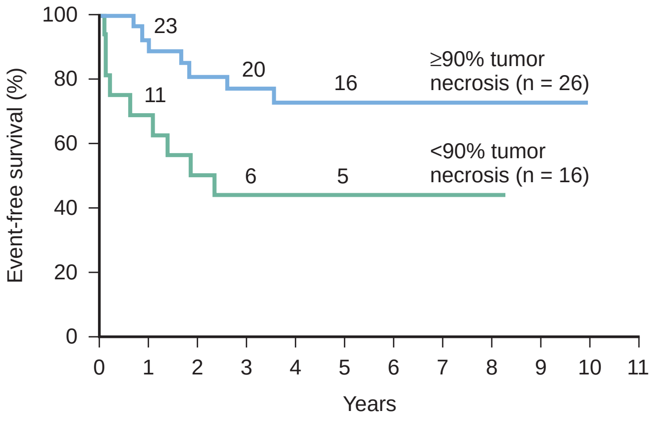

Figure 62-11 Representative event-free survival curve of patients with localized osteosarcoma greater than or equal to 90% *(blue line)* or less than 90% *(green line)* tumor necrosis after neoadjuvant chemotherapy. *(Modified from Goorin AM, Schwartzentruber DJ, Devidas M, et al: Presurgical chemotherapy compared with immediate surgery and adjuvant chemotherapy for nonmetastatic osteosarcoma: Pediatric Oncology Group Study POG-8651.* J Clin Oncol *21:1574–1580, 2003.)*

Radiographic parameters have been investigated for correlation with tumor necrosis and outcome. A decrease in FDG-PET standard uptake value (SUV) before and after neoadjuvant chemotherapy is correlated with histologic response. Neither the change in SUV nor absolute SUV after neoadjuvant chemotherapy has a statistically significant association with OS in localized osteosarcoma. The lack of statistical significance may be due to investigation in only a small population of patients,[127] and larger studies are needed to determine whether FDG-PET responses are predictive of outcome in osteosarcoma. Various MRI techniques including dynamic contrast-enhanced MRI[128] and diffusion-weighted MRI[129] show promise for potential to predict histologic response.

Additional prognostic factors have been identified in localized osteosarcoma. In many cases these factors are not consistently demonstrated to be statistically significant across studies. This may be due to a small effect size and, as a result, the need for large studies to identify a factor as being statistically related to outcome. In other cases, differences in measurement or categorization contribute to variable results across studies.

Tumor size has been identified as a significant prognostic factor by multivariate analysis in several studies.[52,53,113,120] However, other studies have not found this patient variable to be predictive of outcome.[118,130-132] One possible explanation for this conflict is variability in the definition of tumor size and measurement techniques. Some studies evaluate absolute tumor length, others use relative (to the entire bone) tumor length, and still others base analyses on tumor volume. Most studies showing size to be a significant predictor of outcome on multivariate analysis have measured tumor volume.[53,113,120] However, the volume that distinguishes small, low-risk tumors from large, high-risk tumors varies among studies. In summary, further studies using standard measurement techniques and risk criteria need to be conducted before tumor size can be used as a clinically significant predictor on which to counsel patients or base therapeutic decisions. The prognostic significance of tumor size might be caused by the influence of tumor size on resectability. In other words, larger tumors may confer a poorer prognosis because it is less likely that the tumor will be completely resected with wide margins.

Several studies have found an association between tumor site and outcome, with axial and proximal appendicular primary tumors having a worse prognosis than distal extremity tumors.[52,53,110,113,120,133-136] However, there are potential interactions between tumor site and other osteosarcoma prognostic factors. In particular, site and size are likely to be associated. A distal extremity osteosarcoma is likely to be noticed at a smaller size because of the relative lack of soft tissue. More importantly, the higher risk sites, such as axial skeleton, are also those for which a complete resection is less likely.

Elevated LDH and alkaline phosphatase levels at the time of diagnosis are associated with a poorer prognosis.[53,118,119] In one study,[118] the EFS of patients with a normal alkaline phosphatase level at diagnosis was 88%, whereas it was 46% for patients with an elevated alkaline phosphatase level. There are several issues that limit the usefulness of LDH and alkaline phosphatase as prognostic indicators. First, elevated levels are not consistently associated with a poorer prognosis in all studies. Second, elevations in LDH and alkaline phosphatase levels confer only a modestly increased relative risk (1.5 for LDH and 2 for alkaline phosphatase) of a poor outcome.[119]

Other prognostic factors that have been reported to be significant in a limited number of studies are age and gender, with older age and male gender being associated with a worse outcome.[52,53,137,138] Chemotherapy toxicity, represented by grade 3 or 4 mucositis, has been found to be correlated with improved OS.[138,139] A single study from the Children's Oncology Group (COG) identified a high body mass index at the time of diagnosis as a risk factor for inferior survival.[140]

As noted earlier, histologic subtype may be a prognostic factor. P-glycoprotein positivity, loss of heterozygosity at the *RB1* locus, and high ezrin expression have been identified as possible biology-based predictors of a poor outcome.[141,142] These prognostic factors are discussed more extensively (see "Biology").

In summary, the extent of tumor necrosis is the most reliable prognostic indicator in localized, completely resected osteosarcoma. Additional factors correlated with a poorer outcome include older age, less chemotherapy toxicity, larger tumor size, axial tumor site, elevated LDH and alkaline phosphatase levels, and high body mass index. However, for prognostic factors other than tumor necrosis to be utilized for risk stratification, further validation is required in large populations who received uniform therapy. Identification of reliable prognostic factors available at the time of diagnosis is a research priority in osteosarcoma. Biologic efforts such as TARGET (see "Genomics" under "Biology") and further investigation of imaging characteristics are most likely to provide robust predictors of outcome.

Metastatic and Relapsed Disease

The OS for patients with relapsed disease is poor, with most series showing a 25% OS at 5 years.[6,7,114] As with primary osteosarcoma, the most significant prognostic factor for postrelapse survival is the ability to achieve complete resection of all disease sites. In one report of 162 patients with initially localized osteosarcoma who developed recurrent disease, the 5-year projected OS was 39% for those who had complete resection of all disease and 0% for those who did not.[6] With isolated pulmonary metastases, prognosis is significantly influenced by the number of pulmonary nodules and whether there is unilateral or bilateral pulmonary disease.[6,7,114] In particular, having more than one pulmonary nodule at relapse conveys a worse prognosis. An additional prognostic factor is the duration of remission. Patients experiencing relapse less than 24 months after initial diagnosis have a worse outcome.[6,114] Finally, use of chemotherapy is associated with a slightly improved postrelapse prognosis,[7] particularly in patients with unresectable disease.[6] Patients who experience second and subsequent recurrences have a 5-year OS rate of about 15%. As with the initial recurrence, the duration of relapse-free interval, the number of lesions at recurrence, and the ability to resect recurrent disease are all associated with outcome.[143]

Local recurrence warrants special mention because of its dismal prognosis. The 5-year DFS is 0% to 15%.[115,116,144,145] Local recurrence is almost always associated with concurrent or delayed pulmonary metastasis.[115] In one series, the outcome of patients with local recurrence was strongly influenced by the presence or absence of systemic metastases at the time of local recurrence. The 5-year DFS was 25% for patients without systemic metastases at the time of local recurrence, and it was 0% for those with systemic metastases.

The outcome and prognostic factors for metastatic disease present at diagnosis are similar to those for relapsed disease. The 5-year OS of patients presenting with primary metastatic disease is 20% to 30%.[4,146] One exception to the poor prognosis for patients with metastatic disease is skip metastases. In patients with skip metastases, OS is 50%, even when pulmonary metastases are also present.[60] Higher OS has been reported in some chemotherapy trials, possibly because of therapy efficacy or shorter periods of follow-up.[147] An important predictor of a poor outcome is the inability to achieve complete surgical remission. Similarly, patients with metastases to more than one site or more than one organ are at increased risk for death from disease.[4,146] Lymph node metastasis at the time of diagnosis is uncommon, occurring in less than 5% of patients. Lymph node involvement at the time of diagnosis is associated with larger tumor size and an extraskeletal primary lesion. OS at 5 years for those with lymph node metastasis at diagnosis is 10%.[148] In one study, an alkaline phosphatase level higher than 500 IU/L was significantly associated with poor prognosis on multivariate analysis.[146]

BIOLOGY

Structural chromosomal alterations, loss of tumor suppressor function, and oncogene amplification have all been described in osteosarcoma. In addition, alterations in specific proteins contribute to chemotherapy resistance and metastatic behavior. A summary of genes altered in osteosarcoma is presented in Table 62-4.

Cell of Origin

Genetically engineered murine models of osteosarcoma have helped define the cell of origin for osteosarcoma. Lineage-specific models have demonstrated that osteosarcoma can arise from mesenchymal stem cell progenitors, osteoblast progenitors, and osteoblasts. In these lineage-specific genetically engineered mouse models, osteosarcoma develops with the highest penetrance and shortest latency when derived from osteoblast progenitors whereas mesenchymal stem cell progenitors give rise to a larger proportion of poorly differentiated soft tissue sarcomas.[149] A case report of osteosarcoma arising from donor cells after allogeneic stem cell transplantation suggests that mesenchymal stem cells can give rise to osteosarcoma in humans as well.[150]

TABLE 62-4 Genes Implicated in Osteosarcoma Pathogenesis and Biologic Progression

Gene	Alteration	Gene Function	% of Sporadic Osteosarcoma
RB1	Deletion, inactivation	Cell cycle control	70
TP53	Mutation, inactivation	Apoptosis Response to DNA damage Cell cycle control	50
MDM2	Gene amplification	TP53 regulation	10-15
COPS3	Gene amplification	TP53 regulation	25
CDKN2A	Deletion, promoter methylation	Cell cycle control through inhibition of CDK4-CCND1	15-20
MET	Increased expression	Motility Invasion	60
FOS	Increased expression	Proliferation Possibly, differentiation	60
MYC	Gene amplification	Proliferation	40
ABCB1	Increased expression	Efflux of chemotherapeutic agents	25-45
DHFR	Increased expression	Folate metabolism; MTX target	60% relapsed tumors
ERBB2	Increased expression	Growth factor receptor	40
Ezrin	Increased expression	Membrane cytoskeleton linker, facilitates metastasis	92
FAS	Decreased expression	Apoptosis	60% pulmonary metastases lack FAS
Reduced folate carrier	Decreased expression	MTX transport	65
IGF1R	Increased expression	Growth factor receptor, proliferation	Unknown

MTX, Methotrexate.

Genomics

Osteosarcomas contain complex genomic aberrations, suggesting the involvement of multiple genes in osteosarcoma development. Copy number abnormalities, changes in ploidy, and structural rearrangements are seen in all high-grade osteosarcomas. It is a tumor type in which chromothripsis has found to occur frequently.[151] Homogeneously staining regions and marker, double-minute, and ring chromosomes are seen in most tumors.[152,153] A representative karyotype and Circos plot are shown in Figure 62-12. Nonclonal changes, often superimposed on clonal aberrations, are present in many tumor specimens.[81] Several comprehensive next-generation sequencing projects are underway, including one being conducted as part of the National Cancer Institute sponsored Therapeutically Applicable Research to Generate Effective Treatments (TARGET) project. The nonclonal complex nature of the osteosarcoma genome makes the interpretation of genomic data difficult and the identification of candidate genes implicated in a significant proportion of osteosarcomas challenging.[154,155]

Osteosarcoma DNA ploidy ranges from diploid to hexaploid.[152] Spectral karyotyping (SKY) of osteosarcomas reveals an average of 39 chromosomal rearrangements/tumor.[156] Chromothripsis is the simultaneous occurrence of multiple somatic rearrangement events during one single cellular episode. In nine osteosarcoma samples, three (33%) had evidence of chromothripsis.[151] Chromoplexy is a related mechanism of chromosomal rearrangement in which series of interrelated rearrangements affect multiple chromosomes.[157] Preliminary results of an ongoing comprehensive next-generation sequencing study found evidence of chromoplexy in most osteosarcoma samples studied.[158] Pilot studies have demonstrated the feasibility of using detection of patient-specific translocations to track disease burden in patients with osteosarcoma and other solid tumors.[159] Whether this method for detection of minimal residual disease burden will have prognostic implications in osteosarcoma as it has in leukemia remains to be determined.

Multiple genomic techniques have been applied to the assessment of copy number alterations in osteosarcoma. Traditional and spectral karyotype permitted the initial identification of genomic complexity and copy number alterations in osteosarcoma. More sophisticated techniques such as array comparative genomic hybridization (CGH) and single nucleotide polymorphism (SNP) arrays have permitted the identification of recurrently amplified and deleted regions.[154] In almost all CGH analyses, gains are more common than losses.[160-164] Amplified regions consistently seen in a significant proportion of tumors and across studies include 1q21-q24, 6p11.2-p12, 8q21.3-q24, 17p11.2-p12 (high-level amplification), 1p, 1q21,

5p14, and 6p12-21.3. Commonly seen deletions include 2q and 6q and chromosomes 9, 10, and 13q. Copy number alterations are also present in other regions but have been reported in a small proportion of cases or single studies only. Loss of 13q14[161] and gain of 8q (8q21.3-q22 or 8cen-q13)[160] have been associated with a worse prognosis, and 5q loss[161] has been associated with a better prognosis, although these findings have not been replicated. Higher-detail analysis with fluorescence in situ hybridization (FISH), quantitative polymerase chain reaction (PCR) assay, or array CGH has revealed that amplification and deletion patterns are complex, in that individual genes in an amplified region may not be amplified.[165]

Importantly, candidate genes have been identified via assessment of copy number in osteosarcoma. The region 12q13-14, which is amplified in 10%[160,162] of osteosarcomas, contains multiple potential oncogenes, including *MDM2*. In the commonly amplified region 17p11.2-p12, candidates *PMP22, TOP3A, MAPK7,* and *COPS3* display high levels of amplification in more than 50% of cases using semiquantitative PCR assay and microsatellite markers.[166,167] *RB1* is located at 13q14, a region that is lost in many osteosarcomas.[152,153] *MDM2* and *COPS3* amplifications and *RB1* loss are discussed further later. Three groups have identified a recurrent focal deletion at 3q13.3 including the candidate tumor suppressor gene *LSAMP.*[168-170] The *MYC* gene, located at 8q24.1, is amplified in as many as 40% of osteosarcomas. Amplification of 8q24 containing *MYC* and of 12q14 harboring CDK4 and a higher overall degree of loss of heterozygosity have been associated with a poorer outcome.[171] As with other prognostic factors in osteosarcoma, the prognostic significance of these copy number alterations needs to be validated in larger, prospectively conducted clinical studies.

Investigation into the relationship between aberrations in microRNAs and osteosarcoma pathogenesis and prognosis are in their infancy.[172-174] Definitive conclusions await research with large numbers of osteosarcoma samples and more robust statistical methodologies.

Tumor Suppressors

RB1

The retinoblastoma gene *RB1*, located at 13q14, was the first tumor suppressor gene identified and is one of the most frequently altered genes in osteosarcoma. As noted earlier (see "Etiology"), the second most common tumor in patients with hereditary retinoblastoma who carry germline *RB1* mutations[33] is osteosarcoma. *RB1* abnormalities are also present in most sporadic osteosarcomas. *RB1* inactivation is believed to contribute to osteosarcoma tumorigenesis through its role in cell cycle control and possibly through its regulation of differentiation and apoptosis.

Hereditary retinoblastoma is a condition in which individuals with a heterozygous germline *RB1* mutation develop retinoblastoma, a malignant tumor of the embryonal neural retina, with 90% penetrance.[175] Germline *RB1* mutations can be sporadic or inherited. *RB1* germline mutations in patients who develop bilateral tumors are usually small deletions or frameshift mutations resulting in a null protein,[176] whereas 40% of *RB1* germline mutations in patients with unilateral tumors are in-frame point mutations.[176] The cumulative incidence of a second malignancy by 50 years after the initial retinoblastoma diagnosis is 51%. Approximately 50% of the second malignancies developing in patients with hereditary retinoblastoma are osteosarcomas.[32,177] Both osteosarcomas and retinoblastomas occurring in patients with hereditary retinoblastoma have somatic loss of the normal *RB1* allele, with resulting complete absence of a functional RB1 protein.[33,178,179]

Somatic alterations in the *RB1* gene are seen in most sporadic osteosarcomas. Loss of heterozygosity at the *RB1* locus is seen in 65%[34,142] of sporadic osteosarcomas. Structural changes, usually associated with loss of heterogeneity, are present in 30% to 40%[34,180,181] of tumors, and homozygous deletions are seen in 23%[182] of tumors. Point mutations are rare and are present in only 6% of cases.[34] Overall, 70% of sporadic osteosarcomas have at least one *RB1* abnormality,[34] and many tumors have a combination of *RB1* alterations. *RB1* gene alterations are generally not seen in low-grade bone tumors.[34] There is some evidence that the initially mutated allele is usually of paternal origin and the allele that undergoes deletion is maternally derived.[183] Decreased RB1 expression is seen in about 50% of osteosarcomas,[184] but changes in RB1 expression are not correlated with *RB1* gene alterations.[34] For example, in some tumors with *RB1* loss of heterogeneity, RB1 protein levels are not reduced.

Some studies have found an association between *RB1* loss of heterogeneity and a poorer prognosis.[34,142] However, these studies were based on univariate analyses in relatively small populations and another study had contradictory results.[185] Theoretically, *RB1* inactivation could contribute to a poorer prognosis through increasing the expression of thymidylate synthase and dihydrofolate reductase, consequently increasing resistance to antimetabolites,[186] an important component of osteosarcoma therapy.

As reviewed by Classon and Harlow,[187] RB1 is a key regulator of the G1 to S cell cycle transition. RB1, by binding and thereby inhibiting the E2F family of transcription factors, blocks the transition from the G1 to the S phase of the cell cycle. RB1 is regulated by cyclin-dependent kinases (CDKs), particularly CDK4 and CDK6, which interact with CCND1. These CDK-CCND1 complexes phosphorylate RB1. RB1 phosphorylation inhibits the RB1-E2F interaction, allowing transcriptional activation by E2F, which leads to progression from G1 to S (Fig. 62-13). RB1 probably also controls cell cycle progression through chromatin remodeling, as reviewed by Khidr and Chen.[188] In particular, the RB1-E2F complex, by interacting with histone deacetylases, histone methyltransferases, and DNA methylases, contributes to the inactivation of E2F target genes during G0 and G1.

Genetically engineered *Rb1* null mouse models implicate Rb1 in regulation of cellular differentiation and

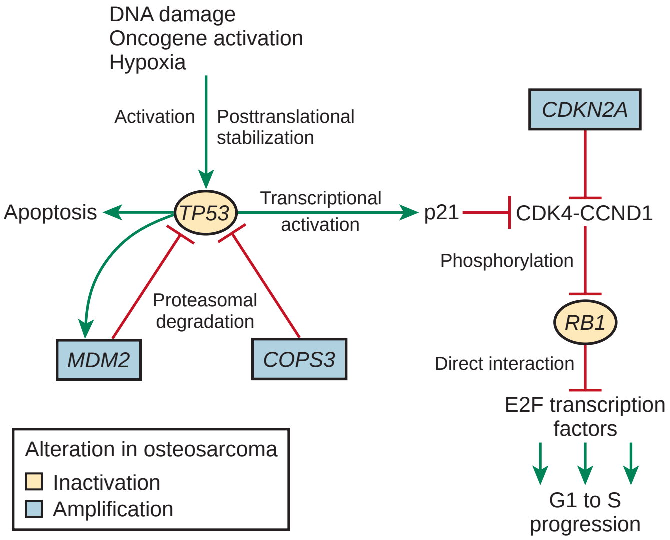

Figure 62-13 Selected regulators and effectors of *TP53* and *RB*. Alterations present in osteosarcoma are highlighted in *yellow* and *blue*.

apoptosis. *Rb1* deletion in mice results in embryonic lethality due to a placental defect.[189] When rescued from the placental defect, abnormal bone development is noted, and this appears to be due to increased proliferation in osteoblast cells combined with a failure in terminal osteoblastic differentiation.[190] Through interaction with CBFA1, a key transcriptional regulator in osteoblasts, RB1 induces osteogenic differentiation.[191] Loss of RB1 in osteoblast precursors appears to result in dedifferentiation, as demonstrated by an increased propensity for adipogenic differentiation.[192] The significance of RB1 differentiation and apoptosis roles in tumorigenesis in general and osteosarcomagenesis in particular is not clear.

TP53

There is convincing evidence that abnormal TP53 function is one of the central events in osteosarcomagenesis. Patients with Li-Fraumeni syndrome, who carry heterozygous germline *TP53* mutations, are predisposed to osteosarcoma. Somatic alterations in the *TP53* gene are found in a significant percentage of sporadic osteosarcomas. Furthermore, several different transgenic mouse models, with altered or absent TP53 function, develop osteosarcoma. Finally, components of the TP53 regulatory and effector pathways, *MDM2* (murine double-minute 2), *CDKN2A* (cyclin-dependent kinase inhibitor 2A), and *COPS3* (COP9 constitutive photomorphogenic homolog subunit 3) are also frequently perturbed in osteosarcoma, particularly in tumors lacking *TP53* mutations.

Of cancers arising in patients with Li-Fraumeni syndrome, 10% are osteosarcoma, making osteosarcoma the second most common tumor in Li-Fraumeni syndrome.[33] In addition to osteosarcoma, patients with Li-Fraumeni syndrome are predisposed to breast cancer, various soft tissue sarcomas, brain tumors, and various carcinomas. *TP53* germline mutations are present in 7% of osteosarcoma patients who have a personal history of multiple cancers but who do not meet Li-Fraumeni diagnostic criteria.[193] Individuals with Li-Fraumeni syndrome have germline mutations in *TP53* located throughout the gene, although approximately 75% of the mutations are in exons 5 to 8,[194] which encode the DNA-binding domain of the TP53 protein. Tumors arising in patients with Li-Fraumeni syndrome typically have loss of the normal *TP53* allele.[195]

Somatic alterations of the *TP53* gene are present in 20% to 50% of sporadic osteosarcomas.[37,196-204] Despite the prevalence of somatic *TP53* mutations in sporadic osteosarcomas, germline *TP53* mutations are rare in patients with sporadic osteosarcoma without a personal or family history of multiple cancers.[205,206] The wide range in the reported frequency of somatic *TP53* alterations in sporadic osteosarcoma is the result of small study size, differences in techniques of ascertainment, and varying definitions of an abnormal result. *TP53* point mutations are present in 20% to 30% of osteosarcomas.[37,197,200-202] As with *TP53* mutations in other cancer types, missense mutations constitute approximately 75% of osteosarcoma point mutations.[207] Point mutations are present throughout the *TP53* coding sequence, although, as with Li-Fraumeni syndrome germline mutations, approximately 73% occur in exons 5 to 8.[201] The initial *TP53* abnormality to be recognized in osteosarcoma was gross rearrangements of the *TP53* gene.[199] Gross rearrangements are present in 15% to 25% of cases.[197,198,200] Studies that evaluated *TP53* for both point mutations and gross gene rearrangements have found that almost 50% of osteosarcomas examined have aberrant *TP53*.[200,203] Because mutant TP53 protein usually accumulates in cells because of an increased half-life,[208] TP53 immunohistochemistry has been used to screen for *TP53* mutations in osteosarcoma. By immunohistochemistry, 15% to 25% of osteosarcomas have TP53 abnormalities,[196,204] reflecting the fact that immunohistochemistry has a relatively low sensitivity for detecting *TP53* mutations. Approximately 50% of osteosarcomas with *TP53* point mutations have loss of the normal allele.[201]

Several genetically engineered mouse models with dysfunctional or absent *Tp53* develop osteosarcoma. In a genetically engineered mouse model in which *Tp53* and *Rb1* deletion is restricted to osteoblasts, osteosarcoma develops with a high penetrance and short latency.[209,210] Mice homozygous for null *Tp53* develop a variety of tumors. Although lymphoma and hemangiosarcoma are the most common tumor types seen, 4% of the mice develop osteosarcoma.[211] Mice heterozygous for null *Tp53* develop tumors at 25% the rate and at an older age than homozygous null mice, but 25% of the tumors that develop are osteosarcomas.[212] Osteosarcomas are much more common in mice genetically engineered to be heterozygous for a common cancer-associated *Tp53* mutation, R172H. Almost 50% of these mice develop osteosarcoma, usually associated with hematogenous metastases.[213] Several other mouse models heterozygous for mutant *Tp53* develop osteosarcoma at a rate of 20% to 30%. Metastases are common in these models as well.[214,215] Transgenic mice expressing the SV40 T antigen from different promoters[216,217] develop osteosarcoma at a rate of approximately 70%. The mechanism of transformation in the SV40 T antigen–expressing models probably involves the inactivation of Tp53 and Rb1.

In other cancers, *TP53* mutation status has been associated with proliferation, response to chemotherapy, and outcome. In osteosarcoma, the response to chemotherapy is equivalent in *TP53* mutant and *TP53* wild-type osteosarcomas.[218] Several studies have examined the impact of *TP53* mutation on survival in osteosarcoma. Only one study, in 30 patients, showed a worse survival in patients whose tumors had *TP53* mutations.[203] The remainder of the studies did not show a relationship between *TP53* mutation status and outcome.[196,200,218,219] Finally, *TP53* mutations are not more common in metastatic disease than in localized disease.[201] Actually, the *TP53* mutation status of primary and metastatic tumors tends to be concordant.[201]

As reviewed by Levine[208] and Vogelstein and colleagues,[220] *TP53* mutations and structural alterations lead to transformation by interfering with TP53 tumor suppressor functions and, possibly, by producing a TP53 protein that has gained oncogenic function. TP53 tumor suppressor activities include cell cycle control and induction of apoptosis. Several forms of cellular stress, including DNA damage, hypoxia, shortened telomeres, and oncogene activation lead to TP53 posttranslational stabilization and TP53 activation. After activation, TP53 binds DNA and promotes the transcription of several genes, including *CDKN1A* and *MDM2*. As in other tumor types, the *TP53* mutations seen in sporadic osteosarcomas and Li-Fraumeni syndrome are concentrated in the DNA-binding domain and interfere with the transcriptional activity of the protein.[207] TP53 prevents progression from the G1 phase to the S phase of the cell cycle through the actions of one of its target genes, *CDKN1A*. The CDKN1A protein inhibits the CDK4-CCND1 complex, which in turn keeps RB1 in an unphosphorylated state. Unphosphorylated RB1 binds E2F transcription factors, preventing progression into the S phase (see Fig. 62-13).[220] TP53 also plays a regulatory role in the G2 to M cell cycle checkpoint. Another inhibitor of CDK4-CCND1 is CDKN2A. CDKN2A abnormalities are also seen in osteosarcoma (see later).

As with TP53-mediated cell cycle control, TP53-mediated apoptosis is triggered by DNA damage. In addition, oncogene overexpression and *RB1* inactivation stimulate TP53-mediated apoptosis. The pathways involved in TP53-mediated apoptosis are not fully understood. However, they likely involve proapoptotic proteins whose genes are targets of TP53 transcriptional activation, including *BAX, PMAIP1,* and *TP53AIP1*.[220]

TP53 inactivation allows cells to progress through the cell cycle and escape apoptosis, despite the presence of DNA damage. Consistent with this observation, the presence of a *TP53* mutation in osteosarcoma is significantly correlated with a greater level of genomic instability.[37] Thus promotion of genomic instability and the resultant accumulation of secondary mutations in oncogenes or tumor suppressors is yet another mechanism of transformation in *TP53* mutant tumors.

TP53 Regulators: *MDM2* and *COPS3*

The regulators of *TP53* activity, *MDM2* and *COPS3,* are amplified in a proportion of osteosarcomas. MDM2 inhibits TP53 activity by direct interaction with the TP53 DNA-binding domain and by transporting TP53 to the cytoplasm.[221-223] In addition, MDM2 ubiquitinates TP53, targeting it for proteasomal degradation. MDM2-mediated ubiquitination is enhanced by DNA damage.[224] The *MDM2* gene, located at 12q14, is amplified in 10% to 15% of osteosarcomas.[197,203,204,225-227] Usually, *MDM2* amplification occurs in tumors without *TP53* mutations, and thus *MDM2* amplification acts as an alternative mechanism of TP53 inactivation. There is limited evidence that *MDM2* amplification is more common in parosteal and other forms of low-grade osteosarcoma.[165,228,229]

COPS3, located at 17p11.2, a frequently amplified region in osteosarcoma, is a subunit of the COP9 signalosome. The COP9 signalosome interacts directly with TP53 and, through phosphorylation, targets TP53 for interaction with MDM2 and degradation by the 26S proteasome.[230] *COPS3* gene amplification is present in 25% to 30% of osteosarcomas.[231,232] Increased COPS3 expression through alternative mechanisms is present in some tumors lacking *COPS3* gene amplification.[231] Like *MDM2* amplification, COPS3 overexpression may be an alternative mechanism of *TP53* inactivation. *TP53* mutations are present in a small proportion of *COPS3*-amplified osteosarcomas.[231,232]

CDKN2A and *CDKN2D*

As described earlier, CDKN2A, like the TP53-inducible protein CDKN1A, is an inhibitor of the CDK4-CCND1 complex. As with CDKN1A, inhibition of CDK4-CCND1 by CDKN2A prevents progression from the G1 to the S phase. Ten to 20 percent of osteosarcomas have *CDKN2A* homozygous deletion,[197,202,203,233] and in another 5% to 10% the *CDKN2A* promoter is methylated. Similarly, by immunohistochemistry, 16% of osteosarcomas lack CDKN2A protein expression.[234] *CDKN2A* deletions appear to be more common in osteosarcomas grown in cell culture[235] but seem to be less common in osteosarcomas with *RB1* abnormalities, possibly because the two alterations have a similar effect on cell cycle control.[233] Few studies have evaluated the coexistence of *TP53* mutations and *CDKN2A* deletions in osteosarcomas. There is limited evidence that the two abnormalities occur simultaneously.[203]

CDKN2D is an alternatively spliced product of the gene encoding *CDKN2A*. CDKN2D inhibits MDM2 by direct binding.[236] Thus loss of CDKN2D leads to increased MDM2-mediated TP53 degradation. As a consequence of the gene structure, the 10% to 20% of osteosarcomas with *CDKN2A* homozygous deletion also lack functional CDKN2D.

RECQ DNA Helicases

As noted earlier, osteosarcoma incidence is increased in three autosomal recessive cancer predisposition syndromes caused by RECQ DNA helicase mutations, Rothmund-Thomson syndrome, Werner syndrome, and

Bloom syndrome. The overlapping but distinct clinical features and specific nature of osteosarcoma predisposition in these syndromes has already been discussed (see "Etiology"). Whereas germline *RECQL4* mutations predispose patients with these syndromes to osteosarcoma, somatic *RECQL4* mutations are not present in sporadic osteosarcomas.[237]

Patients with Rothmund-Thomson syndrome caused by mutations in *RECQL4*[238] develop osteosarcoma with a prevalence of approximately 30% and probably do not have an increased susceptibility to other types of cancer.[239] Interestingly, osteosarcoma occurs only in the 60% of patients with Rothmund-Thomson syndrome who have truncating or inactivating *RECQL4* mutations.[38] On the other hand, patients with Bloom and Werner syndromes, caused by mutations in *RECQL2* and *RECQL3,* respectively,[240,241] are prone to a wide variety of cancers, and osteosarcoma represents less than 10% of the cancers occurring in these patients.[40,41] Why *RECQL4* mutations, in contrast to *RECQL2* and *RECQL3* mutations, specifically increase the risk for osteosarcoma is unknown.

The mechanism whereby loss of function of RECQ DNA helicases results in tumor development generally and in osteosarcoma in particular are not well understood. Proposed RECQ functions that could be related to tumor formation include participation in DNA recombination, maintenance of chromosome stability, recovery from DNA replication collapse, initiation of DNA replication, and telomere processing. The three RECQ DNA helicases mutated in cancer predisposition syndromes have overlapping but not identical functions. In vitro cell culture and mouse models of *RECQL4* mutant Rothmund-Thomson syndrome display increased chromosomal instability with high rates of aneuploidy.[242] Bloom and Werner syndrome models have abnormally high rates of homologous recombination events, with accumulation of recombination intermediates.[243] Studies with the *Xenopus RECQL4* homologue have suggested that RECQL4 participates in the initiation of DNA replication.[244] Several lines of evidence have indicated that the RECQ helicases likely play an essential role in reestablishing DNA replication after disruption of the replication fork.[243] Finally, WRN may be involved in telomerase-independent telomere maintenance.[243,245]

WWOX

WWOX encodes a WW domain containing oxoreductase. This class of proteins has a wide variety of functions including regulation of protein degradation, transcription, and splicing. There is evidence from other cancers that *WWOX* can act as a tumor suppressor. Mice carrying a homozygous deletion of *Wwox*[246] develop osteosarcoma at a rate of 30% prior to premature death at 4 weeks postnatal age.[246] Thirty percent of human osteosarcoma samples have *WWOX* deletions, and 60% have reduced or absent WWOX expression. WWOX interacts directly with RUNX2, a regulator of osteoblast differentiation. In osteosarcoma cell lines deficient in WWOX expression, forced WWOX expression results in decreased RUNX2 expression, decreased proliferation, decreased invasion, and a reduction in xenograft viability.[247,248]

Developmental Pathways and Stem Cell Programs

Wnt Pathway

The Wnt pathway is active in bone development. Activating mutations in *LRP5* (low density lipoprotein receptor–related protein 5), which encodes an Wnt coreceptor (with frizzled4), cause high bone mass whereas inactivating *LRP5* mutations result in decreased bone mass. Despite multiple investigations into Wnt pathway activity in osteosarcoma, it remains unclear how and whether perturbations in Wnt pathway activity contribute to osteosarcomagenesis.[249] The majority studies conclude that overactive Wnt signaling contributes to osteosarcoma formation. For example, deletion of the Wnt inhibitory factor, *Wif1,* in mice increased osteosarcoma formation after irradiation.[250] However, there are conflicting reports such as a genome-wide expression study finding downregulation of the Wnt pathway in osteosarcoma.[251]

USP1

USP1 encodes a deubiquitinating enzyme that deubiquitinates inhibitor of DNA-binding/differentiation (ID) proteins, preventing their degradation. ID proteins or inhibitors of DNA binding are basic helix-loop-helix transcription factors that have been shown to inhibit differentiation and maintain a stemlike state. In a small group of osteosarcoma tumors, expression of USP1 and ID2 were correlated and 7 of 14 tumors had high USP1 and ID2 expression. In U2OS and 143B osteosarcoma cell lines USP1 knockdown decreased ID1, ID2, and ID3 protein levels; decreased expression of the stem cell markers e-cadherin and fibronectin; and increased expression of markers of mature osteoblasts. *USP1* knockdown decreased the number of cells in S phase of the cell cycle and decreased xenograft formation.[252] If the results of this single study are validated, USP1 inhibition is a potential therapeutic avenue for osteosarcoma. Development of USP1 inhibitors is of interest owing to potential for activity in a wide variety of cancers, including lung cancer.[253,254]

Oncogenes

Multiple cell surface receptor oncogenes are expressed and activated in osteosarcoma. It appears as though coexpression and coactivation of multiple cell surface receptors is a feature of osteosarcoma cell lines.[255,256] Whether this phenomenon is also present in primary osteosarcoma tumors is not yet known. *MET, FOS, ERBB2,* and *MYC* are oncogenes that have been extensively investigated in osteosarcoma.

MET

MET, a receptor tyrosine kinase, was first identified and noted to be oncogenic in a transformed human osteosarcoma cell line. In the 1970s, Rhim and colleagues[217] treated a human osteosarcoma cell line with *N*-methyl-*N′*-nitronitrosoguanidine (MNNG), a chemical carcinogen. MNNG treatment resulted in a morphologic change and the acquisition of in vivo tumor-forming capacity. Subsequent studies have shown that the transforming event is formation of a fusion oncogene, *TRP-MET,* which leads to high levels of MET expression.[257,258]

MET is highly expressed in human osteosarcomas and osteosarcoma cell lines. The exact proportion of osteosarcomas that have high MET expression varies, depending on the detection method used. By Western blotting, 60% to 88% of osteosarcoma tumor specimens and 100% of osteosarcoma cell lines display high levels of MET protein.[259,260] Immunohistochemical analysis yields more variable results, with 35% to 75% of osteosarcomas highly expressing MET.[261,262] The quantitative PCR assay also demonstrates elevated MET expression in all osteosarcoma tumor specimens and cell lines studied.[263] Of note, the benign bone tumors osteoblastoma and nonossifying fibroma do not express MET but chondroblastoma and giant cell tumors do express MET.[259,260,262] When primary and metastatic tumors from the same patient are compared, metastatic tumors have higher MET expression than the primary tumors, suggesting a role for MET in osteosarcoma metastasis.[259,261,264] The mechanism of elevated MET expression in osteosarcoma is not known. When evaluated, *MET* gene amplification does not appear to be present in osteosarcoma.[259]

Functional studies in cell lines have contributed to the understanding of MET-transforming roles in osteosarcoma. Expression of MET carrying an activating mutation or overexpression of MET by lentiviral transfection transforms normal osteoblasts.[263] Despite a high level of MET expression, MET is not activated in the absence of its ligand, hepatocyte growth factor (HGF).[265] An autocrine-paracrine loop may cause MET activation in human osteosarcomas in vivo.[260] Addition of HGF to MET-expressing osteosarcoma cell lines results in MET activation, activation of downstream signaling intermediates MAPK and AKT, and increased invasive growth.[265,266] MET-HGF interaction in other model systems induces proliferation and enhances motility, cellular changes that frequently precede metastasis.[267]

As reviewed by Trusolino and Comoglio,[267] the MET receptor, and HGF, turn on cellular programs that lead to invasive growth. Downstream mediators of MET activity include cadherins, integrins, and metalloproteinases. The ultimate outcome of MET activation includes loss of cell-cell adhesion, increased cell motility, and extracellular matrix degradation. Physiologic requirements for invasive growth include organogenesis, tissue regeneration, and wound healing. Inappropriate activation in cancer cells leads to tissue invasion and metastasis.

FOS

FOS was initially identified as osteosarcomagenic through investigation of the FBJ murine virus. Mice inoculated with FBJ murine virus develop osteosarcomas that are pathologically similar to human tumors.[268] The viral protein responsible for transformation after infection with FBJ murine virus has almost complete homology with the murine c-Fos protein expressed from the murine Fos gene.[269] Transfection of a functional, highly expressed *FOS* gene transforms fibroblasts.[270]

Further evidence that c-Fos overexpression can induce osteosarcomas has been provided by transgenic mouse models. Transgenic mice in which *Fos* is expressed from a major histocompatibility complex (MHC) class I promoter develop osteosarcoma with 100% penetrance.[271] In these mice, *Fos* is highly expressed in both osteoblasts and osteosarcomas. Transgenic mice in which the gene is expressed from a different universally expressed promoter, human metallothionein, also develop osteosarcomas but at a much lower frequency,[272] suggesting that there is a dose-response relationship between the extent of FOS overexpression and the development of osteosarcoma.

FOS is overexpressed in human osteosarcoma tumor specimens. By immunohistochemical analysis, 50% to 60% of human osteosarcomas express high levels of FOS protein.[273,274] Only 20% of benign bone tumors have immunohistochemical positivity for FOS, and the level of FOS immunohistochemical staining in benign tumors is not as high as in osteosarcomas.[234] When compared with normal tissues and nonosteosarcomatous lesions, FOS expression, as assessed by immunohistochemistry, is 150%.[274] FOS RNA levels are increased in 40% of osteosarcomas.[275] One study has found an association between FOS expression and the occurrence of metastasis or recurrence,[275] but another did not.[273]

Although it is known that FOS, a member of the AP1 transcription factor complex, is an important mediator between extracellular signaling and transcriptional activation in normal bone development, it is not known exactly how FOS overexpression contributes to osteosarcomagenesis. Induction of *Fos* expression in osteoblasts alters CCND1 levels and increases entry into the S phase.[276] Wagner[277] has noted that AP1 complex activity is regulated by vitamin D, transforming growth factor β, and parathyroid hormone, all of which are important factors influencing bone formation, growth, and healing. In particular, FOS appears to play an essential role in enchondral ossification. *Fos* null mice have significant osteopetrosis, suggesting that FOS activity is required for normal osteoclast function.[278,279]

Insulin-like Growth Factor

As noted earlier (see "Etiology"), there is epidemiologic evidence for a link between normal bone growth and osteosarcoma, including the coincidence of osteosarcoma peak incidence with maximal linear growth in adolescence and the higher rate of osteosarcoma in larger dog breeds.[280] The observed epidemiologic links between osteosarcoma and bone growth could have alternate explanations. Osteosarcoma in large-breed dogs could be caused by the underlying genetics of breed founders rather than by rates of bone growth. Nevertheless, as central mediators of normal linear bone growth and cellular proliferation in general, insulin-like growth factor 1 (IGF-1) and its receptor, insulin-like growth factor 1 receptor (IGF1R), have been investigated in osteosarcoma. In vitro and in vivo data have supported a possible role for IGF-1 and IGF1R in osteosarcoma proliferation and invasion.

IGF-1 and IGF1R are members of the family of insulin-like growth factors and insulin-like growth factor receptors. The other ligands in the IGF-1 family are IGF-2 and insulin. There are three tyrosine kinase receptors in the family, IGF1R, IGF2R, and the insulin receptor. IGF1R is the primary target of IGF-1 and the most thoroughly studied insulin-like growth factor receptor in osteosarcoma. IGF2R also appears to be highly expressed across a number of osteosarcoma cell lines.[256] Other key modulators of IGF1R activity are the insulin-like growth factor binding proteins (IGFBPs).[281] Knockout mice lacking IGF-1 or IGF1R are approximately half the size of normal mice and have delayed formation of their ossification centers.[282] Several humans with fetal growth restriction and postnatal short stature were found to have mutations in IGF1R.[283,284]

Competitive binding assays, affinity labeling experiments, and Northern and Western blot studies have demonstrated expression of IGF1R by osteosarcoma cell lines.[285,286] IGF-1 expression is variable across osteosarcoma cell lines.[287] Although less thoroughly studied than IGF-1, IGF-2 appears to be expressed by osteosarcoma cells.[286,288] There has been limited investigation into IGFBPs in osteosarcoma, but one study has shown that IGFBP3 transcription is augmented in MG-63 osteosarcoma cells in response to IGF-1.[289]

In osteosarcoma cell lines, IGF1R is not activated in the absence of its ligand.[290] Addition of IGF-1 to osteosarcoma cells in culture results in IGF-1R activation,[291] activation of IGF-1R downstream signaling, including AKT and ERK activation,[291] and increased proliferation[285,287,288] One study has shown that IGF-2 is also mitogenic for osteosarcoma cell lines and that this effect is mediated by binding to IGF2R.[288]

Multiple mechanisms of IGF1R inhibition in vitro and in vivo suppress osteosarcoma growth and invasion. In a number of different osteosarcoma cell lines, antibodies to IGF1R decrease osteosarcoma proliferation in a dose-dependent manner.[285,287,288,292] In some cases, antibody treatment causes 100% inhibition of IGF-1–induced proliferation. Forced expression of IGFBP5 or IGFBP3 by genetic or chemical mechanisms results in decreased IGF-1 expression, increased expression of differentiation markers, and decreased proliferation of osteosarcoma cells.[293,294] In vivo interruption of growth hormone by hypophysectomy or growth hormone–releasing hormone antagonism leads to a dramatic decrease in osteosarcoma xenograft tumor size and metastasis.[248,256,286,295]

IGF-1 and IGFBP3 levels in patients with osteosarcoma are different than established age- and gender-matched normal values, with 68% of patients having low IGF-1 levels. IGF-1 and IGFBP3 levels are not correlated with clinical variables such as metastasis and outcome.[296] Phase I studies of octreotide pamoate, a growth hormone antagonist, in patients with osteosarcoma have shown a 50% decrease in serum IGF-1 levels. However, there were no clinical responses to octreotide pamoate. There are several possible explanations that could reconcile these clinical findings, with evidence suggesting an important role for the IGF axis in osteosarcoma. The behavior of IGF-1 and IGF1R in osteosarcoma models may not accurately represent osteosarcoma in patients. More likely, IGF-1 may act in a paracrine rather than endocrine manner, so that IGF-1 serum levels are not representative of the tumor milieu. Alternatively, IGF1R activation in osteosarcoma in vivo may be mediated by IGF-2 or the extent of IGF1R activation may not be determined by ligand concentration. Finally, osteosarcoma biology is likely to be heterogeneous, with the IGF axis being important in some tumors but not in others. Early phase IGF1R antibody trials included an insufficient number of osteosarcoma patients to determine whether these drugs are effective in osteosarcoma.[297] It is not clear whether IGF1R antibodies will continue to be developed given lack of activity of these drugs in carcinomas. IGF1R kinase inhibitors continue to be developed.

ERBB2

The *ERBB2* protooncogene encodes the human epidermal growth factor receptor 2, a receptor tyrosine kinase in the epidermal growth factor receptor family. *ERBB2* is amplified in 20% of breast cancers,[298] and ERBB2 protein is expressed in a similar proportion of breast cancers.[299] In breast cancer, *ERBB2* amplification or ERBB2 expression is associated with a poorer prognosis. Trastuzumab, an anti-HER2 therapeutic antibody, improves survival in patients with *ERBB2*-amplified tumors.[300]

ERBB2 protein levels are increased in 30% to 40% of osteosarcomas.[196,301-303] Initial studies raised the possibility of an association between ERBB2 expression and a worse prognosis, but this finding was not confirmed in later studies.[304] Some investigators have found evidence of *ERBB2* gene amplification in osteosarcoma,[302] but others have not.[301,305,306] As discussed later (see "Treatment"), these findings led to a COG study, AOST 0121, that evaluated the feasibility of adding trastuzumab to multiagent chemotherapy. Eligible patients were those with high-risk metastatic osteosarcoma whose tumors were ERBB2 positive. Outcome in ERBB2-positive patients was similar to that of historical controls, suggesting limited activity of trastuzumab in ERBB2-positive osteosarcoma.[303]

MYC

The *MYC* gene, located at 8q24.1 is amplified in 7% to 10% of osteosarcomas when assessed by Southern blotting.[275,307] The more sensitive technique, array CGH, detects *MYC* amplification in 44% of osteosarcomas.[164,275,307,308] MYC mRNA and protein levels are increased in a similar proportion of osteosarcomas, and MYC expression might be correlated with metastasis. MYC, when complexed with MAX, activates the transcription of a number of genes, perhaps as many as 15% of all genes. Downstream effects of MYC transcriptional activation include proliferation, cell growth, inhibition of differentiation, and apoptosis. Exactly how MYC regulates these diverse cell processes and how *MYC* amplification leads to cancer is an area of active investigation.[309,310] One percent of mice with conditional *Myc* overexpression from the EμSRa promoter develop osteosarcoma.[311] With the recent development of BET bromodomain inhibitors, MYC has become a potential therapeutic target.[312]

Determinants of Metastasis

One of the defining features of osteosarcoma is its tendency to metastasize early, hence the need for systemic chemotherapy in all patients. Metastasis is a complicated process that involves motility, migration, degradation of extracellular matrix, extravasation, survival during transit through vasculature, invasion, and growth. Given the complicated nature of the process, many factors are likely to play a role in metastases, but it is difficult to decipher the specific contribution of each. Several of the factors that have been more extensively studied in the context of osteosarcoma will be discussed.

Chemokine ligand 12 (CXCL12) is a cytokine-like protein expressed on the surface of vascular endothelial cells. Through binding to its chemokine receptor, CXCR4, it plays a role in cytoskeleton rearrangement, adhesion to endothelial cells, and chemotaxis.[313,314] Involvement of the CXCR4/CXCL12 pathway has been implicated in the metastatic potential of several cancers, including rhabdomyosarcoma and lymphoma.[315-317] CXCR4 mRNA has been shown to be expressed in osteosarcoma and associated with the presence of metastases at the time of diagnosis.[318-320] In vitro assays have shown that migration of osteosarcoma cells expressing CXCR4 follows an CXCL12 gradient and that their adhesion to endothelial and bone marrow stromal cells is promoted by CXCL12 treatment.[320] This study also provided a rationale for the propensity of osteosarcoma to metastasize to the lung, where CXCL12 concentration is high, and demonstrated prevention of pulmonary metastasis in a murine model by the administration of a CXCR4 inhibitor, suggesting molecular strategies inhibiting this axis as a therapeutic target.[320]

Ezrin is a membrane-cytoskeleton linker protein that allows direct cellular interactions with the microenvironment, facilitating signal transduction through growth factor receptors and adhesion molecules, thereby regulating cell migration and metastasis, among other processes.[141] In an orthotopic model of murine osteosarcoma, ezrin expression was threefold higher in the more aggressive K7M2 cell line, which correlated with its metastatic potential when compared with the less aggressive K12 cell line.[321,322] In follow-up experiments, ezrin expression was found to provide an early survival advantage for pulmonary metastatic osteosarcoma, which is in part mediated by AKT.[141] Ezrin exists in phosphorylated (active) and unphosphorylated (inactive) states.[323] Establishment of osteosarcoma metastases in a mouse model is dependent on fluctuation between the active and inactive forms of ezrin.[324] Ezrin phosphorylation at threonine 567 is mediated in part by protein kinase C in osteosarcoma cell lines. The identification of protein kinase C as a mediator of ezrin phosphorylation and the discovery of small molecules that inhibit ezrin phosphorylation make ezrin a potential therapeutic target for osteosarcoma.[325] A significant correlation between high ezrin expression and poor outcome in osteosarcoma has been shown, with shorter DFS and higher risk for metastatic relapse, supporting the animal model data.[141]

Overexpression of MET and its ligand hepatocyte growth factor, in osteosarcoma cell lines suggests a role for MET in its metastatic phenotype. Binding of the ligand to the MET ligand receptor stimulates both cell proliferation and motility, features associated with metastasis.[259,326] In a study of 17 osteosarcoma tumor samples, 60% expressed the MET ligand receptor at high levels.[259] When primary and metastatic tumors from the same patient are compared, metastatic tumors have higher MET expression than the primary tumors, indicating its role in potentiating the metastatic phenotype of osteosarcoma.[259-261]

FAS is a transmembrane receptor that activates the extrinsic cell death pathway on stimulation by its ligand, FASL. There is increasing evidence that a variety of tumor types that escape from apoptosis may enhance the ability of tumor cells to metastasize.[327] Studies in an osteosarcoma murine xenograft model with a high rate of pulmonary metastasis have suggested that decreased FAS expression enhances osteosarcoma metastasis. Therapies enhancing FAS expression inhibit the development of metastases in this model system. However, evidence that perturbations in FAS are a generalized mechanism of enhanced metastatic potential in osteosarcoma is limited.

The SAOS2 LM6 cell line was produced by serially passaging a human osteosarcoma cell line, SAOS2, through immunodeficient mice until pulmonary metastasis developed reliably and rapidly after tail vein injections. FAS protein and mRNA levels are lower in the SAOS2 LM6 metastasis–producing cell line compared with the seldom-metastasizing parental cell line SAOS2.[328] Furthermore, when SAOS2 LM6 FAS expression is increased through transfection, the number and size of pulmonary metastases developing after tail vein injection decrease.[329] FAS expression can also be induced by interleukin-12 (IL-12).[328] Intrapulmonary aerosolized IL-12 gene therapy after SAOS2 LM6 tail vein injection increases FAS expression in metastatic tumors and inhibits the development of pulmonary metastases.[330-333] Interestingly, ifosfamide and IL-12 display a synergistic relationship when used together in this model system, possibly because of ifosfamide-induced expression of FASL.[330]

FAS expression has been evaluated in human osteosarcoma pulmonary metastases from 28 patients. FAS was not expressed in 60% of the tumors, and the remaining 40% had only weak FAS expression.[334] Further study is needed to confirm that decreased FAS expression contributes to the metastatic potential of osteosarcoma occurring in humans and in osteosarcoma models other than the SAOS2 LM6 model.

Other factors that likely play a role in osteosarcoma metastases include expression of matrix metalloproteinases[335] and other degradative enzymes. The expression of these enzymes is necessary to degrade the extracellular matrix, permitting extravasation into the vasculature.

Biologic Markers of Response to Chemotherapy

The response of osteosarcoma to chemotherapy is evident in the change in patient survival resulting from its administration. Defining "response" is somewhat more difficult. Chemotherapy response in osteosarcoma is typically used to refer to the degree of necrosis in the definitive surgical resection specimen. The degree of necrosis seen in that specimen is a consistent predictor of patient survival across studies, as described elsewhere in this chapter. In the original description of the grading system, a grade I response was considered indicative of no histologically visible response to chemotherapy. Subsequently, this was specified as being less than 50% necrosis, because untreated osteosarcomas could have as much as 25% spontaneous necrosis. It was therefore believed that necrosis more than double this amount would be attributable to a chemotherapy effect. Numerous biologic studies have been performed correlating a particular marker with the necrosis grading. In some of these studies, the necrosis grading was used as a surrogate for EFS, with the anticipation that these will correlate. The advantage of necrosis grading in this context is that the data are available much sooner than mature EFS data. In other contexts, the necrosis grading is used as a marker of chemotherapy response. Complicating these analyses, the standard of care in osteosarcoma is multiagent chemotherapy. Factors that only affect responsiveness to a single agent may not be predictive in the context of multiagent chemotherapy. Given these limitations, relating a genetic alteration to necrosis grading may provide a more robust relationship with chemotherapy response than survival, because survival may be influenced by many factors other than chemotherapy response. Similarly, necrosis grading may be a better marker of response than radiographic response in osteosarcoma, because the mineralized matrix of an osteosarcoma prevents radiographically visible shrinkage of the tumor.

Because chemotherapy has had a dramatic effect on the outcome of osteosarcoma, it is perhaps intuitive to assume that genetic alterations that produce drug resistance would be associated with inferior chemotherapy response and patient survival. Along these lines, perhaps the most extensively studied prognostic marker is the expression of P-glycoprotein (PGP) or multidrug resistance protein 1 (MDR1). This is a transmembrane adenosine triphosphate–dependent efflux pump protein encoded by the multidrug resistance gene (*ABCB1,* formerly *MDR1*), which is responsible for the efflux of numerous chemotherapeutic agents from the malignant cell. In the context of osteosarcoma, the most important drug that can be effluxed by MDR1 is doxorubicin, although etoposide is also a substrate. Immunohistochemistry and reverse-transcriptase (RT)-PCR quantification studies have explored MDR1 and *ABCB1* expression in osteosarcoma and demonstrated overexpression of MDR1 in 23% to 45% of tumors, with decreased survival reported for patients with MDR1-positive tumors[336-341] in initial studies. Of interest, although many of these studies demonstrated a correlation with outcome, several key studies did not demonstrate a relationship with the necrosis grade. This suggests that use of necrosis grading as an early marker of outcome may not always be appropriate in the context of some biologic markers. A meta-analysis has proposed that MDR1 is associated with an increased risk for disease progression.[342] Although the early literature suggested that MDR1 may be a marker of drug resistance and aggressiveness in osteosarcoma, this finding has not been verified consistently across studies.[336-339,341] In addition, a prospective clinicopathologic cooperative group study has concluded that there is no correlation between MDR1 expression and percentage of osteosarcoma tumor necrosis after induction chemotherapy or EFS in localized osteosarcoma.[343] Overexpression of *ABCB1* has also been explored with regard to its prognostic relevance. Although a small pilot study has shown a trend toward a worse outcome in patients exhibiting high levels of *ABCB1* expression,[344] a larger prospective investigation did not identify a correlation between ABCB1 messenger RNA expression and prognosis in osteosarcoma patients, with patients with either very low or very high levels of ABCB1 having a relatively poor outcome.[345]

High-dose methotrexate (HDMTX) with leucovorin rescue is a major component of current protocols for the treatment of osteosarcoma.[110,346] HDMTX is vastly more effective than conventional dose methotrexate in the treatment of osteosarcoma, a finding that is not observed in other malignancies treated with MTX, implying a mechanism of intrinsic MTX resistance within osteosarcoma tumor cells.[347] In experimental systems, resistance to methotrexate can occur through a variety of mechanisms, including impaired intracellular transport of the drug via the reduced folate carrier, upregulation of dihydrofolate reductase, and diminished intracellular retention caused by decreased polyglutamylation. Studies have demonstrated that impairment of drug influx as a result of decreased expression and mutations in the reduced folate carrier gene is the major basis of intrinsic resistance; 65% of osteosarcoma tumor samples were found to have decreased reduced folate carrier expression at the time of initial biopsy.[347] In contrast, dihydrofolate reductase overexpression was seen relatively infrequently at initial biopsy, in only 10% of tumor samples, compared with 62% of the tumors examined at the time of definitive surgery or relapse, suggesting dihydrofolate reductase overexpression as the major mechanism of acquired MTX resistance in osteosarcoma.[347]

In vitro induction of HMGB1 expression in osteosarcoma cells prevented apoptosis. HMGB1 is a chromatin-binding nuclear protein that may be involved in chemotherapy resistance in other cancers.[348] Evaluation of HMBG1 in human osteosarcoma samples has not been performed. Other potential mechanisms of drug resistance include alterations in multidrug resistance protein expression, topoisomerase II, glutathione *S*-transferases, DNA repair, DNA damage response, drug metabolism or inactivation, and reduced intracellular delivery. Few studies have been performed in osteosarcoma to indicate whether these processes play a role in defining chemotherapy response.

In other studies, necrosis after chemotherapy has been used as a marker of response, and investigators have attempted to identify genetic signatures predictive of response. In each of these studies, a large number of genes were required to define a profile of response. The studies reported using 60 genes,[349] 104 genes,[350] and 45 genes[351] to distinguish between responders and nonresponders. This may be related to the small sample sizes used in each of these studies. Alternatively, the lack of robust clustering may be caused by the heterogeneity of osteosarcoma itself. Lack of robust clustering on gene expression profiling appears to be a property of non–translocation–associated sarcomas, a result of their high levels of genetic complexity.

Translational Science

Bone metabolic pathways are of interest in osteosarcoma given that this is a tumor arising from osteoblasts and osteoblast precursors. Zoledronate is a nitrogen-containing bisphosphonate and the most potent of its class. It inhibits the development of osteolytic and osteoblastic bone lesions.[342,352] Preclinical models have shown cytotoxicity against osteosarcoma cell lines.[353,354] In vivo models in mice inoculated intravenously with the spontaneous murine osteosarcoma cell line POS-1 have shown prolonged survival when treated with single-agent zoledronate.[355] Moreover, combination with ifosfamide has shown more activity than either agent alone in preventing tumor recurrence, improving tissue repair, and increasing bone formation.[356] Bisphosphonates may also improve bone integrity after limb salvage surgery.[357,358]

Receptor activator of nuclear factor κB ligand (RANKL, also known as tumor necrosis factor ligand superfamily member 11 [TNFSF11]) and its receptor RANK have the physiologic function of regulating bone turnover. In response to RANKL-RANK binding, osteoclast precursors differentiate and become activated resulting in bone resorption.[359] An antibody against RANKL, denosumab, has been approved by the U.S. Food and Drug Administration (FDA) for treatment of osteoporosis. RANK is expressed in 57% of human osteosarcomas, most human osteosarcoma cell lines, and 70% of canine osteosarcomas, including two of two canine osteosarcoma skin metastases.[360,361] RANKL is expressed in 75% of human osteosarcoma tumor specimens, and the strength of expression is associated with prognosis.[362] In osteosarcoma cell lines, RANKL activates downstream signaling and modulates gene expression.[361,363] Further evidence supporting activity of the RANK-RANKL pathway in osteosarcoma is provided by a transgenic mouse model of osteosarcoma. In an osteosarcoma mouse model created by expression of the SV40 T/t antigen from the osteocalcin promoter, heterozygous deletion of *Prkar1a* accelerates development of osteosarcoma via increased *Rankl* gene expression. A subset of human osteosarcomas have low *PRKAR1A* expression and high *RANKL* expression.[365] In vivo studies of denosumab are limited by the fact that the antibody does not recognize murine or canine Rankl. To circumvent these limitations, in vivo studies have utilized other approaches to inhibit Rankl activity, including Rank gene therapy, which creates a decoy receptor for Rankl, RANK-Fc, a chimeric protein that efficiently binds Rankl, or SiRNA directed against Rankl. In a murine orthotopic OS model, Rank gene therapy decreased primary and metastatic tumor burden: mice receiving this therapy did not develop osteosarcomatous lung metastases whereas 80% of control mice developed lung metastases.[365] A study by the same group using RANK-Fc confirmed these original findings.[366]

The phosphatidylinositol 3’ kinase/mammalian target of rapamycin (PI3K/mTOR) pathway is a central signaling pathway contributing to proliferation and survival in many cancers. The pathway has been recognized to contribute to proliferation, drug resistance, and metastasis in osteosarcoma. Expression of mTOR and p70S6K, an indicator of mTOR activation, is present in 70% to 80% of osteosarcomas, and the level of expression has been correlated with overall and disease free survival.[367] Activation of PI3K-AKT signaling is downstream of several biological processes involved in osteosarcoma metastasis such as Ezrin expression.[368] Micro-RNA-221, expressed at high levels in osteosarcoma targets PTEN, increases cell survival, decreases apoptosis, and induces cisplatin resistance.[369] The dual PI3K/mTOR inhibitor BEZ235 and the alpha selective PI3K inhibitor BYL719 induce cell cycle arrest and decrease tumor formation in vivo.[370,371] The clinical trial experience with mTOR inhibition in osteosarcoma is limited, and PI3K inhibitors have not been evaluated in this disease. There have been rare but dramatic responses to mTOR inhibition in patients with advanced, refractory osteosarcoma.[372] In a study using a sequenom assay to identify cancer-associated mutations in osteosarcoma, 3 of 89 tumors were found to have mutations in *PIK3CA*, the PI3K catalytic subunit.[373] A comprehensive next-generation sequencing study of 59 osteosarcoma samples thus far presented only in abstract form, identified PI3K/mTOR pathway alterations in 25% of osteosarcomas.[158]

GD2 is a cell surface sialic acid containing glycosphingolipid expressed normally in the central nervous system, peripheral nerves, and melanocytes. In neuroblastoma, anti-GD2 antibody given with cytokines to promote antibody-dependent cell-mediated cytotoxicity significantly improves EFS and OS.[374] More than 90% of osteosarcomas express GD2, and the intensity of expression, in most samples, is greater than that seen in neuroblastoma.[375,376] In the phase I/Ib trial of the murine anti-GD2 antibody, 14.2G2a, plus interleukin-2, one of two osteosarcoma patients treated had a complete response persisting for 8 months.[377]

There is mixed evidence regarding the role for immunotherapy in osteosarcoma. Completed clinical trials utilizing general immune stimulation with interferon α (IFN-α)[378] and inhaled granulocyte-macrophage colony-stimulating factor (GM-CSF)[379] did not demonstrate significant activity of either approach. Dendritic cell therapy has shown anti-osteosarcoma activity in one mouse model, particularly when pulsed in vitro with irradiated tumor and administered in a minimal residual disease setting.[380] However, in a clinical study of dendritic cell vaccination there was a lack of T-cell response and no evidence of clinical benefit.[381] Immune surveillance by T cells may delay or prevent the development of metastasis, as seen in a mouse model.[382] In a single study in a murine xenograft model, chimeric antigen receptor T cells expressing interlukin-11Rα treatment resulted in regression of pulmonary metastases.[383]

TREATMENT

Local Control

Definitive surgical treatment of osteosarcoma (discussed more extensively in Chapter 49 "Pediatric Surgical Oncology") has two components: tumor resection and reconstruction. Tumor resection is essential for cure of osteosarcoma. Ten-year survival in patients with macroscopic residual tumor is less than 15%, even with multiagent chemotherapy.[52,384] Tissue margins on the resection specimen should be wide. Although the exact tissue margin required is not known, wide margins are generally defined as 2 to 5 mm for soft tissue and 2 to 3 cm for bone marrow. Marginal and intralesional margins are associated with a poor outcome and an increased risk for local recurrence.[53,385] As noted earlier (see "Natural History and Prognosis"), an additional factor increasing the risk for local recurrence and poor outcome is a poor histologic response to chemotherapy. In one study, inadequate margins and a poor histologic response to therapy were independent predictors of local recurrence.[386] In this study, having both a poor histologic response to therapy and inadequate margins dramatically increased the risk for local recurrence.[386]

Options for limb reconstruction include limb-sparing techniques that use allografts or fixed or expandable endoprostheses. Currently, 75% to 80% of patients with nonaxial tumors are treated with limb-sparing surgery.[110,115] As long as the resection margins are adequate, limb-sparing techniques do not change EFS or OS.[119,132] Because of the significant cosmetic impact, amputation and rotationplasty are often reserved for those patients whose tumors are not amenable to limb-sparing techniques. Occasionally, however, patients will opt for amputation or rotationplasty because of their advantages, which include a lower incidence of repeated surgical revisions and a greater ability to participate in high-impact activities.[387] Benefits of endoprostheses over allografts include a shorter postoperative recovery time and a lower incidence of perioperative complications. Allografts have the important advantage of allowing preservation of the growth plate. The relative strengths and weaknesses of the various surgical options are discussed further later (see "Complications of Therapy") and in Chapter 49, "Pediatric Surgical Oncology."

The optimal surgical approach should be determined by a multidisciplinary team that includes a radiologist, oncologist, and orthopedic surgeon with experience in the treatment of bone tumors. Adequate imaging, usually MRI, is required to determine which surgical procedures will produce sufficient margins. Finally, a good understanding of the patient's and family's priorities is needed to provide appropriate counseling.

Chemotherapy for Localized Disease

The use of neoadjuvant and adjuvant chemotherapy has increased the OS of patients with localized high-grade osteosarcoma from 20% to 70% to 75%. The most active chemotherapeutic agents for localized osteosarcoma are HDMTX with leucovorin rescue, doxorubicin (Doxo), and cisplatin (CP). In addition, ifosfamide and etoposide have demonstrated efficacy in metastatic osteosarcoma. Institutional and cooperative group studies have attempted to identify the optimal combination of active agents, the most effective drug dosing, and the impact of dose intensity and schedule on outcome and toxicity (Tables 62-5 and 62-6). Much has been learned from these studies. However, important questions remain, including the ability to improve high-risk disease outcomes through chemotherapy intensification, the role of immune modulators in osteosarcoma therapy, and whether there is additional benefit of adding ifosfamide and etoposide to first-line therapy for localized disease.

Chemotherapy and Outcome

It has not always been clear that chemotherapy is effective in osteosarcoma. Successful treatment of osteosarcoma with chemotherapy was first reported in the literature in the early 1970s. Jaffe and colleagues[109] treated 20 patients with adjuvant HDMTX and vincristine (VCR). They noted 1 death in 20 patients compared with 14 expected deaths, based on historical controls. In 12 patients with completely resected primary tumors, there was 1 death, which was 6 fewer than predicted by historic controls.[109] Cortes and colleagues[388] saw similar dramatic improvements in OS and EFS in 21 patients treated with surgery and Doxo. The Memorial Sloan-Kettering Cancer Center (MSKCC) has reported an OS of 75% with neoadjuvant HDMTX containing multiagent chemotherapy.[123] Other groups reported improved survival compared with historical controls with adjuvant CP and Doxo[389] or adjuvant multiagent chemotherapy containing Doxo.[390] However, in other studies, chemotherapy did not appear to improve outcome. Lange and colleagues[391] treated 20 patients with completely resected nonmetastatic osteosarcoma with HDMTX, VCR, and Doxo and observed an OS of only 26%, a rate similar to that of untreated historical controls.

Randomized controlled trials comparing chemotherapy and observation have been conducted for several reasons, despite the positive results of some early chemotherapy studies. First, the improved outcome observed with chemotherapy could have been caused by an improved outcome for all patients unrelated to chemotherapy. Advances in diagnosis and surgical approach could have improved outcome, irrespective of other therapies provided. Results of a randomized controlled trial at the Mayo Clinic,[134,392] in which the EFS was 42% in both treated and untreated patients, supported this theory. Second, because of the lack of a control group, the favorable results of these early chemotherapy trials could have been caused by patient selection.[393]

Two randomized controlled trials published in the mid-1980s confirmed the effectiveness of chemotherapy

TABLE 62-5 Randomized Controlled Trials of Chemotherapy for Nonmetastatic Osteosarcoma

Group	Year	Regimen(s)	No. Patients	EFS/ DFS	Primary Objective(s)	Results/Conclusions
Mayo[134]	1984	HDMTX/VCR vs. observation	38	42%	Demonstrate superior outcome with adjuvant chemotherapy.	1. EFS and OS equivalent in chemo and observation arms. 2. EFS/OS in observation arm better than historic controls. 3. Power inadequate to detect a difference. 4. Natural history may be improving.
POG[394]	1986	HDMTX/Doxo/BCD vs. Observation	36	66% 17%	Demonstrate superior outcome with adjuvant chemotherapy.	1. Adjuvant chemotherapy improves outcome. 2. Natural history is not improving.
UCLA[395]	1987	HDMTX/VCR/Doxo/BCD vs. Observation	59	55% 20%	Demonstrate superior outcome with adjuvant chemotherapy.	1. Adjuvant chemotherapy improves outcome. 2. Natural history is not improving.
EORTC-SIOP[450]	1988	HDMTX/Doxo/CTX + adjuvant HDMTX/Doxo/CP vs. HDMTX/Doxo/CTX + adjuvant pulmonary XRT	205	40%	Compare efficacy of adjuvant chemotherapy vs. adjuvant pulmonary XRT.	1. EFS and OS equivalent in all arms. 2. Pulmonary XRT less toxic than chemotherapy.
MSKCC (T10)[412]	1982	HDMTX/BCD/Doxo ±VCR Good response: Continue same Poor response: –HDMTX, +CP, ± VCR	57	93% 96% 91%	Evaluate the effect of VCR on EFS.	1. Improved EFS compared with historic controls 2. VCR has no impact on EFS.
COSS[125]	1988	MTX/Doxo/CP Good response: Continue same Poor response: ifosfamide/CP/ BCD vs. IFN-α MTX/BCD Good response: Continue same Poor response: Doxo/CP	141	58% 49%	Improve survival or decrease toxicity by altering chemotherapy intensity based on tumor response.	1. Lower intensity therapy results in a reduced EFS. 2. Higher-intensity therapy for poor responders does not result in an increased EFS (compared with historic controls).
Rizzoli[118]	1990	MTX/CP Good responders: Continue same Fair response: + Doxo Poor response: + Doxo/BCD HDMTX: 7500 mg/m^2 vs. MDMTX: 750 mg/m^2	127	58% 42%	Compare efficacy of HDMTX and MDMTX.	1. EFS worse in patients receiving MDMTX although result is not statistically significant. 2. Lower intensity therapy for good responders results in a reduced OS of 20%.
EOI[126]	1992	HDMTX/Doxo/CP vs. Doxo/CP	198	41% 57%	Compare efficacy of multiagent regimen and two-agent regimen.	Two-drug regimen as efficacious as multiagent regimen.
EOI[422]	1997	HDMTX/VCR/BCD/Doxo/CP vs. Doxo/CP	407	44%	Compare efficacy of multiagent, prolonged (44 wk) regimen and two-agent shorter (18 wk) regimen.	1. EFS and OS equivalent in both arms. 2. Compliance better in shorter, two-agent regimen.

TABLE 62-5 Randomized Controlled Trials of Chemotherapy for Nonmetastatic Osteosarcoma (Continued)

Group	Year	Regimen(s)	No. Patients	EFS/ DFS	Primary Objective(s)	Results/Conclusions
MSKCC (T12)[112]	1998	HDMTX/BCD Poor response: + Doxo/CP Good response: + Doxo vs. Neoadj.: HDMTX/BCD/Doxo/CP Poor/good response: Continue	73	73% 78%	Improve outcome by intensifying preoperative chemotherapy.	1. Preoperative chemotherapy intensification increases percentage of good responders. 1. EFS is equivalent in both arms. 2. Intensifying preoperative chemotherapy does not increase DFS.
POG[111]	2003	Neoadj.: None Adj: HDMTX/BCD/Doxo/CP vs. Neoadj.: HDMTX/Doxo/CP Adj.: + BCD	106	65%	Compare outcomes of patients treated with or without neoadjuvant chemotherapy.	1. Neoadjuvant chemotherapy does not improve or worsen EFS. 2. Limb salvage rates are similar in both arms.
COG[5,110]	2005	HDMTX/Doxo/CP ± MTPPE ± Ifosfamide	667	63%	Improve outcome by intensifying chemotherapy with ifosfamide, MTPPE or both.	1. OS and EFS were not statistically different between arms on initial analysis. 2. On follow-up analysis OAS is slightly better in patients receiving MTPPE.
EOI[423]	2007	Doxo/CP q3 wk cycles vs. Doxo/CP q2 wk cycles (w/G-CSF)	497	39% 41%	Improve survival by increasing dose intensity.	1. EFS/OAS equivalent in both arms. 2. Toxicity equivalent in both arms. 3. Outcome with two-agent, shorter regimen (this study) significantly worse than with multiagent prolonged regimen (other studies).

Adj., Adjuvant; *BCD*, bleomycin, cyclophosphamide, and dactinomycin; *CP*, cisplatin; *DFS*, disease-free survival; *Doxo*, doxorubicin; *EFS*, event-free survival; *G-CSF*, granulocyte colony-stimulating factor; *HDMTX*, high-dose methotrexate; *IFN-α*, interferon-α; *MDMTX*, moderate-dose methotrexate; *MTP-PE*, muramyl tripeptide phosphatidylethanolamine; *Neoadj.*, neoadjuvant; *OS*, overall survival; *VCR*, vincristine; *XRT*, radiation therapy.

TABLE 62-6 Nonrandomized, Uncontrolled Trials of Chemotherapy in Nonmetastatic Osteosarcoma

Group	Date	Regimen(s)	No. Patients	EFS
CHOP[391]	1982	HDMTX/VCR/Doxo	20	26%
CCG[132]	1997	Neoadj.: HDMTX/VCR/BCD Good responders: Doxo Poor responders: Doxo/CP	268	53% 81% 46%
COSS[133]	1998	Low-risk: HDMTX/Doxo/CP High-risk: HDMTX/Doxo/CP/I	171	66%
Rizzoli[115]	2000	Neoadj.: HDMTX/Doxo/CP Good response: Continue same Poor response: + IE	164	61%
St. Jude[405]	2001	HDMTX/Doxo/I	69	72%
SSG[404]	2003	Neoadj.: HDMTX/Doxo/CP Good response: Continue same Poor response: + I/E	113	63%
ISG/SSG[113]	2005	HDMTX/Doxo/CP/I	182	64%

BCD, Bleomycin, cyclophosphamide, and dactinomycin; *CP*, cisplatin; *Doxo*, doxorubicin; *EFS*, event-free survival; *HDMTX*, high-dose methotrexate; *I*, ifosfamide; *IE*, ifosfamide and etoposide; *Neoadj.*, neoadjuvant; *VCR*, vincristine.

and an unchanged osteosarcoma natural history. In a multiinstitutional study, 36 patients with nonmetastatic fully resected osteosarcoma were randomized to observation or treatment with HDMTX, Doxo, and a regimen of bleomycin, cyclophosphamide, and dactinomycin (BCD).[394] The EFS was 66% in the group treated with chemotherapy but only 17% in the observed patients. Investigators at the University of California, Los Angeles, randomized 59 patients to a similar chemotherapy regimen or observation and obtained almost identical results.[395] Of treated patients, 55% were free of disease at 2 years whereas only 20% of observed patients remained free of disease. Statistically significant improvement in EFS and OS with chemotherapy has remained after long-term follow-up of this study population.[396]

Chemotherapeutic Agents

Cisplatin. In addition to the initially identified agents, HDMTX and Doxo, CP was identified as an active antiosteosarcoma drug in the late 1970s[397] and was rapidly incorporated into multiagent protocols. Adjuvant CP, in combination with Doxo, results in DFS rates at least as high as those seen with adjuvant HDMTX and Doxo.[389] In the past, it was theorized that intraarterial administration of cisplatin directly to the primary tumor might improve local control and survival. However, several randomized trials have failed to show survival gains from the intraarterial administration route,[133,398] despite an increased proportion of tumors with a good histologic response in some studies. Thus, it is now generally accepted that intraarterial administration of cisplatin is not of sufficient benefit to be worth the increased risk and inconvenience, although countervailing opinions remain.[399] Carboplatin has successfully replaced cisplatin in the treatment of some other cancers, but it may be less efficacious than CP in osteosarcoma. In a Pediatric Oncology Group study, presurgical carboplatin produced pathologic tumor responses in only 1 of 37 chemotherapy-naïve patients with metastatic osteosarcoma.[400] On the other hand, patients enrolled on a single-arm St. Jude Children's Research Hospital study in which chemotherapy consisted of carboplatin, ifosfamide, and Doxo[401] had similar outcomes compared with historical populations treated with CP-containing chemotherapy regimens. Carboplatin may have adequate activity in osteosarcoma when combined with some chemotherapy regimens, particularly those containing ifosfamide.

A recently published trial conducted by the Société Française d'Oncologie Pédiatrique (SFOP)[402] has underscored the importance of CP in osteosarcoma therapy. This study had two arms, with different preoperative chemotherapy regimens. In one arm, preoperative chemotherapy was HDMTX and Doxo, and patients in the other arm received HDMTX and combined ifosfamide and etoposide (IE). Patients with a poor histologic response to preoperative chemotherapy in the HDMTX-IE arm received postoperative CP-Doxo and had an EFS of 60%, whereas patients with a poor histologic response in the HDMTX-Doxo arm received postoperative IE without CP and had an EFS of 49%.

Ifosfamide and Etoposide. After demonstration of antiosteosarcoma activity in unresectable or metastatic disease,[403] ifosfamide was incorporated into multiagent treatment protocols for localized disease with the goal of improving outcome[113,115,133,404] or minimizing toxicity.[405] In two separate nonrandomized studies, one conducted at the Rizzoli Institute (Italy) and one by the Scandinavian Sarcoma Group (SSG), patients with a poor histologic response were treated with the IE regimen. In both studies, outcome was improved in patients with a poor response when compared with historical controls.[115,404] However, in a follow-up joint study by the SSG and the Italian Sarcoma Group (ISG), ifosfamide was given to all patients regardless of tumor response and the outcome was similar to that of historical controls.[113] Because none of these trials was randomized, a definitive conclusion regarding the additional benefit gained by adding IE to first-line therapy of localized disease is not possible. In a randomized controlled COG trial, the addition of ifosfamide to Doxo, CP, and HDMTX for patients with localized osteosarcoma did not increase survival.[110] Of note, in this trial, patients were treated with ifosfamide not in combination with etoposide, and ifosfamide was administered in a relatively low dosage (9 g/m^2/course). In another approach to incorporating ifosfamide into osteosarcoma regimens, the ISG conducted the ISG/OS-1 trial in which ifosfamide was administered to all enrolled patients in the neoadjuvant period. The use of ifosfamide in the neoadjuvant period did not improve the proportion of patients with a good histologic response or EFS or OS when compared with appropriate historical populations.[406]

A meta-analysis of osteosarcoma trials found that three-drug regimens, most of which do not contain ifosfamide, and four-drug regimens, most of which do contain ifosfamide, produce equivalent EFS and OS. This outcome does not eliminate a potential role for ifosfamide in osteosarcoma chemotherapy regimens.[407] Ifosfamide may be utilized to decrease the cumulative dose of other chemotherapy agents such as Doxo to decrease toxicity. In addition, studies conducted to date have not adequately addressed whether there is a role for ifosfamide in improving outcomes in high-risk patients. An international, multigroup study, the European and American Osteosarcoma Study Group (EURAMOS), is examining the efficacy of the addition of postoperative IE for improving EFS in patients whose tumors have a poor histologic response to chemotherapy.

Methotrexate. In early protocols, MTX was administered at dosages between 3 and 7.5 g/m^2.[109,123,131] However, methotrexate pharmacokinetics in children result in lower peak MTX levels for a given dosage per kilogram of body weight partly because of faster renal clearance.[408] Since this information became known, most regimens have used a MTX dosage of 12 g/m^2.[110,111] Several retrospective studies have shown a correlation between higher peak methotrexate levels (700 to 1000 μmol/L) and tumor necrosis[80] and DFS.[409] At a methotrexate dosage of 12 g/m^2, more than 90% of patients achieve peak methotrexate levels above 1000 μmol/L.[409,410] However, the only study directly comparing 7.5 g/m^2 and 12 g/m^2

did not demonstrate improved survival with the higher dosage.[411] Moderate MTX dosages (600 to 750 mg/m^2) do not seem to be as effective as high MTX dosages.[118,130] Alkaline intravenous fluids and leucovorin are administered with HDMTX, and MTX levels should be monitored after MTX administration.

Microtubule Inhibitors Vincristine and Eribulin. VCR was used in combination with MTX in the initial chemotherapy study by Jaffe and colleagues[109] because of preclinical data suggesting that VCR potentiated cellular MTX uptake. It is no longer used because a randomized controlled trial has shown no effect on EFS compared with MTX alone.[412] Eribulin is a synthetic analogue of a natural product, halichondrin B, and has a novel mechanism of action when compared with other microtubule inhibitors. Unlike other antimicrotubule drugs that suppress the shortening and growth phases of microtubule dynamic instability, eribulin works by inhibition of microtubule growth.[413,414] When evaluated by the Pediatric Preclinical Testing Program (PPTP), a platform for assessing the activity of novel agents in xenografts of common pediatric malignancies, eribulin had significant activity in osteosarcoma xenografts. Three of six patients with osteosarcoma receiving xenografts had a complete response, one had stable disease, and the remaining two had progressive disease. In a preclinical study with the osteosarcoma cell line U2OS, eribulin affected mitotic spindle centromere dynamics.[415] On the basis of these promising preclinical results, a phase II trial of eribulin in recurrent osteosarcoma is planned.

Bleomycin, Cyclophosphamide, and Dactinomycin. The combination of bleomycin, cyclophosphamide, and dactinomycin (BCD) was initially used by investigators at MSKCC[123] in combination with other active agents. BCD was included in a number of other treatment regimens in a nonrandomized fashion. However, in a direct comparison of BCD and CP in combination with HDMTX, VCR, and Doxo conducted by the Cooperative Osteosarcoma Study Group (COSS), the results of therapy with BCD were equivalent to those with CP.[124] In addition, BCD does not cause tumor regression in patients with previously treated metastatic disease.[416] Because of the equivalency with CP, lack of demonstrated efficacy in metastatic disease, and potential pulmonary toxicity, BCD is no longer included in most osteosarcoma chemotherapy regimens.

Immune Modulators. In vitro, IFN-α decreases the proliferation of osteosarcoma cell lines.[417] In vivo, growth of mouse osteosarcoma xenografts is inhibited by IFN-α.[418] Based on these preclinical data, investigators at the Karolinska Institute in Sweden gave IFN-α monotherapy to patients with localized fully resected osteosarcoma. The EFS was 53%.[419] Because of the impressive EFS in this study, a randomized trial evaluating IFN-α as maintenance after multiagent chemotherapy was conducted by EURAMOS. Results of this study have been presented, and IFN-α maintenance therapy did not improve EFS or OS.[378]

Another immunomodulatory therapy that might have activity in osteosarcoma is muramyl tripeptide phosphatidylethanolamine (MTP-PE). MTP-PE is a liposomal encapsulated bacille Calmette-Guérin cell wall component. It activates macrophages and, in mouse xenografts, induces tumoricidal activity.[420] Adjuvant treatment of osteosarcoma in dogs with MTP-PE alone led to a significantly increased DFS.[421] The addition of MTP-PE to HDMTX, Doxo, and CP was evaluated in a COG randomized controlled trial.[110] In the initial analysis of this study, neither EFS nor OS was statistically significantly improved in patients treated with the addition of MTP-PE or MTP-PE and ifosfamide to standard three-drug HDMTX, CP, and Doxo when compared with those treated with the three-drug combination of HDMTX, CP, and Doxo alone. Interpretation of the study results remains controversial, especially in light of a recently published follow-up analysis of the study data. In this analysis, the addition of MTP-PE to the standard three-drug regimen of HDMTX, CP, and Doxo significantly improved 6-year OS from 70% to 78% but did not significantly improve EFS.[5] At present, the FDA application for approval of MTP-PE is pending and MTP-PE is therefore not currently available.

Neoadjuvant Chemotherapy

Neoadjuvant chemotherapy is an approach in which some of the chemotherapy cycles are given prior to tumor resection and the remaining cycles are given postoperatively. Neoadjuvant chemotherapy in osteosarcoma has several potential benefits. Theoretically, neoadjuvant chemotherapy could increase DFS and OS through earlier treatment of microscopic metastatic foci.[123] From a practical perspective, neoadjuvant chemotherapy provides sufficient time for custom endoprosthesis preparation and other surgical planning. In addition, if sufficient tumor shrinkage occurs, neoadjuvant chemotherapy could make a patient who would have required amputation eligible for limb-sparing surgery. Postoperative healing could also be improved by neoadjuvant chemotherapy because there is less urgency to resume chemotherapy.

Theoretically, the greatest benefit of neoadjuvant chemotherapy is that it permits evaluation of tumor response to chemotherapy, the only clear predictor of outcome in osteosarcoma. Identifying patients with a poorer prognosis combined with subsequent therapeutic interventions could improve outcome. However, at present, there are no known therapeutic interventions that improve outcomes for patients with a poorer prognosis based on histologic response to chemotherapy. If therapeutic interventions that improve outcomes in patients with a poor tumor response to chemotherapy are not identified, the value of neoadjuvant chemotherapy will be diminished.

Neoadjuvant chemotherapy was initially used in MSKCC protocols.[123,412] The OS in patients treated with the MSKCC neoadjuvant protocols was 75% to 93%. Because an OS of 93% was significantly better than outcomes reported with adjuvant chemotherapy, there was initial excitement that neoadjuvant therapy would improve survival. However, a COSS protocol using the neoadjuvant approach, COSS-80, had an EFS of 68%, similar to EFS in ongoing studies of adjuvant chemotherapy.[124] Nevertheless, essentially all protocols after 1980 included, in a nonrandomized fashion, neoadjuvant chemotherapy. In general, EFS in these neoadjuvant protocols was similar to EFS seen in protocols giving only adjuvant therapy.

In the only randomized controlled trial comparing adjuvant and neoadjuvant chemotherapy,[111] OS and EFS were not significantly different for patients receiving adjuvant or neoadjuvant chemotherapy. Other than allowing the identification of a group of patients with a poorer prognosis, there did not appear to be significant additional benefits to neoadjuvant chemotherapy. The number of limb salvage procedures was the same in the adjuvant and neoadjuvant groups. Surgical complications were not reduced by neoadjuvant chemotherapy. Several patients had progression of the primary tumor during neoadjuvant chemotherapy, and a few of these patients developed pulmonary metastasis. Thus patients with clearly documented tumor progression during neoadjuvant chemotherapy should proceed to resection without completing the planned course of neoadjuvant therapy. This is especially true in the case of proximal tumors at risk for becoming inoperable (e.g., a proximal humeral lesion crossing the shoulder joint). On the other hand, chemotherapy-induced swelling of the tumor can sometimes be difficult to distinguish from progressive disease.

Response-Based Therapy

Multiple protocols have attempted to improve outcome in patients with a poorer prognosis by intensifying chemotherapy for this group of patients. In general, poor histologic tumor response after neoadjuvant chemotherapy has been used to stratify patients into an intensified treatment arm. Treatment intensification has generally been through the addition of one or two agents in the adjuvant phase not given during the neoadjuvant phase. For example, in Children's Cancer Group, Rizzoli Institute, and COSS protocols using neoadjuvant therapy consisting of HDMTX and BCD, adjuvant treatment was intensified by adding CP and Doxo.[118,125,132] Similarly, in the MSKCC T10 protocol, CP was administered to intensify therapy after neoadjuvant treatment with HDMTX, BCD, and Doxo.[412] With the exception of the T10 protocol, patients in the poor responder group had a similar outcome to historical controls (who did not get intensified chemotherapy), despite chemotherapy intensification.

In protocols in which both Doxo and CP are given neoadjuvantly, ifosfamide with or without etoposide has been used to intensify adjuvant chemotherapy for patients with a poor histologic response.[113,115,125,404] In the SSG protocol SSGVIII[404] and a recent Rizzoli protocol,[115] HDMTX, Doxo, and CP were given neoadjuvantly and IE was given adjuvantly to poor responders. In the Rizzoli trial, patients did not have a better outcome than historical controls (who did not receive IE intensification), whereas in the SSGVIII trial, outcome was better than historical controls, with an OS of 70% in patients with a poor histologic response.

In a different approach to chemotherapy intensification, COSS divided patients into high-risk and low-risk groups based on tumor size, pathologic subtype, and clinical response to neoadjuvant chemotherapy, measured by results of a bone scan. Patients in the high-risk group were treated with additional ifosfamide, added to the HDMTX, Doxo, and CP therapy. High-risk patients achieved the same outcome as low-risk patients. These results can be interpreted either as an indication that ifosfamide is effective at improving survival in high-risk patients or as indicating that the factors used to define the high-risk group do not actually convey a worse prognosis.[133] In summary, there is no convincing evidence that intensifying adjuvant chemotherapy for patients whose tumors have a poor histologic response results in an improved outcome. The lack of randomized studies addressing this question prevents a definitive conclusion about the usefulness of this approach.

On the other hand, there is fairly clear evidence that attempting to decrease toxicity for low-risk patients whose tumors have a good chemotherapy response by de-intensifying chemotherapy results in a worse prognosis.[118,125] In one arm of COSS-82, neoadjuvant chemotherapy consisted of HDMTX and BCD and, during adjuvant therapy, a lower dose of Doxo (30 mg/m^2 × 2 days) was given than had been used in previous protocols. The EFS was 41% in this arm of the study, which was significantly less than in both the other study arms and in historical controls. In a trial at the Rizzoli Institute, after neoadjuvant therapy with HDMTX and CP, patients with a good response received only further HDMTX and CP. These patients had an EFS of only 27%.

The conclusion of a series of studies by the European Osteosarcoma Intergroup (EOI)[126,422,423] is that a two-drug regimen of Doxo and CP is inferior to regimens that include three or more drugs. In the first and second randomized studies, outcomes in patients treated with CP and Doxo and those treated with regimens containing at least the three drugs were equivalent.[117] However, in these two studies and a third study, in which all patients were treated with Doxo and CP, EFS was approximately 40%, a lower rate than is seen in studies of multidrug regimens conducted by other groups.

Non–Risk-Based Chemotherapy Intensification

There are gains to be made in outcome for all osteosarcoma patients, not just those with high-risk disease. With this in mind, some groups have evaluated the impact of intensifying chemotherapy for all patients. The MSKCC T12 trial randomized patients to a more- or less-intensive neoadjuvant chemotherapy regimen. Patients randomized to the more-intensive study arm received HDMTX, BCD, Doxo, and CP neoadjuvantly and adjuvantly, whereas patients randomized to the less-intensive arm received HDMTX and BCD neoadjuvantly, with adjuvant therapy based on tumor response. Doxo was continued for patients with a good response, with Doxo and CP used for poor responders. EFS was 73% for patients in the less-intensive arm of the study and 78% for those in the more-intensive arm of the study,[110] a difference that is neither clinically nor statistically significant.

The COG conducted a randomized trial to evaluate the impact of adding adjuvant ifosfamide and/or MTP-PE to the initial HDMTX, Doxo, and CP. As noted earlier, in the initial analysis of this trial, neither the addition of ifosfamide nor the addition of MTP-PE significantly improved survival.[110] However, in a follow-up analysis, MTP-PE was shown to improve 6-year OS significantly, by a small margin.[5] As noted, interpretation of these data remain uncertain. As with chemotherapy intensification for poor responders, randomized controlled trials are needed to determine whether additional benefit can be gained from adding ifosfamide, etoposide, or other active agents such as immunomodulators to the core anti-osteosarcoma agents HDMTX, Doxo, and CP.

Dose Density

The most recent EOI study has evaluated the impact on toxicity and survival of shortening the interval between CP and Doxo courses from 3 to 2 weeks. In this randomized trial, patients on the every-2-week arm were supported with granulocyte colony-stimulating factor (G-CSF) between chemotherapy cycles. The EOI found that the shortened interval dosing was equivalent in both toxicity and outcome to the longer interval dosing.[423]

Current Approach to Therapy

Most of the osteosarcoma research groups, COG, SSG, COSS, and the EOI, have collaborated on an international trial, EURAMOS 1. The chemotherapy administered to all patients in the trial initially is neoadjuvant and adjuvant HDMTX, Doxo, and CP (Table 62-7). The objectives of this randomized trial are the following: (1) to determine whether the postoperative addition of IE improves EFS of patients with a poor response to neoadjuvant chemotherapy; and (2) to evaluate whether the postoperative addition of IFN-α after neoadjuvant chemotherapy improves outcome in patients with a good histologic response. All patients will receive a total of 10 weeks of neoadjuvant chemotherapy with HDMTX (four cycles) and Doxo and CP (two cycles). Patients with a poor response will be randomized to continue HDMTX, Doxo, and CP or to continue HDMTX, Doxo, and CP with the addition of IE. Patients with a good response will be randomized to continue HDMTX, Doxo, and CP or to continue HDMTX, Doxo, and CP, with the addition of IFN-α. The results of the good histologic response study arm were reported at the American Society of Clinical Oncology Annual Meeting in 2013. There was no difference in event free or overall survival between those who received IFN-α and those who did not. Only 55% of enrolled patients completed IFN-α therapy per protocol; 45% stopped early due to toxicity. The conclusion of this arm of the study is that, when given as tolerated, IFN-α does not improve outcome in osteosarcoma. The results of the poor histologic response study arm are still not available.[423a]

Initially Metastatic Osteosarcoma

As noted earlier (see "Natural History and Prognosis"), the presence of metastatic disease at the time of initial diagnosis is the most unfavorable prognostic feature. In view of the unfavorable outlook of these patients, strategies that included higher toxicity regimens have been used in an effort to improve patient outcome. The Pediatric Oncology Group (POG)[400] administered carboplatin, 1 g/m^2 as a 48-hour continuous infusion, to patients with initially metastatic osteosarcoma as initial therapy. Only 1 patient had an overall partial response. After researchers separately analyzed the primary and metastatic sites of disease, they found that 3 patients had a partial response of their primary tumor (2 had histologic evaluation of the tumor at definitive surgery, showing between 50% and 90% necrosis), 3 had complete responses, and 1 had partial response of their pulmonary disease. However, 20 of 37 patients had unequivocal progressive disease while receiving carboplatin. After induction, multiagent chemotherapy was administered with a combination of high-dose methotrexate, ifosfamide (2.4 g/m^2/day for 5 days, as a single agent), CP, and Doxo, for a total of 40 weeks. Overall outcome was poor, with an EFS of 24% and OS of 40% at 3 years. Patients with isolated pulmonary metastasis had a more favorable outlook, as in the COSS series, with a 44% 3-year survival. Those with unresectable bony metastases had a particularly poor outcome, 6% survival at 3 years.

A subsequent POG study began therapy with two cycles of high-dose ifosfamide (3.5 g/m^2/day for 5 days) and etoposide (100 mg/m^2/day, also for 5 days).[147] This was based on a prior phase I study of etoposide with escalating dosage of ifosfamide, in which 6 of 13 patients with recurrent osteosarcoma responded to therapy with higher dosage levels of ifosfamide.[424] Induction with ifosfamide and etoposide was followed by multiagent chemotherapy with high-dose methotrexate, CP, and Doxo, as well as three additional cycles of a slightly lower dosage of ifosfamide, 2.4 g/m^2/day for 5 days, and etoposide, 100 mg/m^2/day for 5 days. Surgery of the primary and resectable metastatic sites was encouraged. Of 41 evaluable patients, 2-year progression-free survival was 43%, with an OS probability of 55%. In the limited number of patients studied, survival was similar for

patients with isolated pulmonary metastases, 52% at 2 years, as compared with patients with bone metastases, with or without lung metastases, 58% at 2 years. Toxicity was significant, however, with two toxic deaths, one from gram-negative sepsis and the second from congestive cardiac failure. Eighty-three percent of patients experienced severe neutropenia, with sepsis in 10% (including the septic death) and other bacterial infections in an additional 7%.

In view of the relatively favorable outcome of the IE-containing regimen, it served as the model for the core regimen in the COG study AOST 0121. The ifosfamide dosage utilized was one level lower (2.8 g/m^2/day for 5 days), along with etoposide 100 mg/m^2/day for 5 days because of toxicity observed on the previous trial, and the ordering of the cycles was slightly different. As noted earlier (see "Biology"), the presence of ERBB2 expression in osteosarcoma was believed to confer an unfavorable prognosis and to represent a tumor target. Trastuzumab is a humanized antibody that binds specifically to the ERBB2 protein. Preclinically, it was found to antagonize the function of the growth-signaling properties of the ERBB2 system, signal immune cells to attack and kill tumor targets, and augment chemotherapy-induced cytotoxicity.[425-429] A pivotal randomized phase III trial in women with previously untreated ERBB2-positive metastatic breast cancer has shown a significantly improved response rate and survival for those who initially received trastuzumab along with chemotherapy.[300] Trastuzumab increased the risk for cardiotoxicity when given with anthracyclines. However, trastuzumab cardiotoxicity appears to be reversible on discontinuation of the drug.[430] In view of the possible increased risk for cardiotoxicity, entry into AOST 0121 was limited to the highest-risk patients—those with bone metastases, bilateral lung metastases, or unilateral lung metastases with at least four nodules. In addition, dexrazoxane was administered as a cardioprotective agent prior to bolus doxorubicin. Approximately one third of patients had tumors that expressed ERBB2, and only these patients received trastuzumab. Toxicity data demonstrated that it is feasible to combine trastuzumab with multiagent chemotherapy in osteosarcoma. Clinically significant cardiac events did not occur. Outcome in ERBB2-positive patients was similar to that for ERBB2-negative patients treated with chemotherapy alone and to that for historical controls, suggesting limited activity of trastuzumab in ERBB2-positive osteosarcoma.[303]

More recently the COG conducted a study in patients with initially metastatic osteosarcoma incorporating zoledronate into the same background chemotherapy utilized in AOST 0121. The study assessed the feasibility and safety of adding zoledronate to multiagent chemotherapy. Zoledronate could be successfully combined with chemotherapy. Similar results were obtained in a related study in which pamidronate was combined with chemotherapy.[431] The 5-year EFS and OS in patients with metastatic osteosarcoma treated with chemotherapy and zoledronate were 45% and 62%, respectively.[432] Because of differences in study populations these outcomes could not be compared with prior prospectively studied patients and thus determining the effectiveness of inhibiting bone turnover in osteosarcoma will require additional studies. A trial being conducted by the SFOP may shed some light on this question.

The trial evaluating the addition of MTP-PE to chemotherapy also enrolled patients with metastatic disease (see "Immune Modulators" under "Chemotherapy for Localized Disease"). As in patients with localized osteosarcoma, the 5-year OS in patients with metastatic osteosarcoma randomized to receive MTP-PE plus chemotherapy was slightly better than in those randomized to receive chemotherapy alone. However, this result was not statistically significant.[433] Therefore, as with MTP-PE in localized osteosarcoma, the results of this initial randomized study of MTP-PE are not conclusive. An additional clinical trial of MTP-PE would help clarify the role of this therapy in metastatic osteosarcoma.

In the absence of positive results from any of the clinical trials that have been conducted in the metastatic patient population, the standard approach to chemotherapy in patients with metastatic osteosarcoma is to use treatment protocols utilized in patients with localized disease. Some clinicians will intensify therapy such as by adding ifosfamide and etoposide to a HDMTX, Doxo, and CP based regimen as was done for the COG studies AOST 0121[303] and AOST 06P1.[432]

As with localized osteosarcoma, complete resection of all gross disease, when feasible, is an important part of therapy in metastatic osteosarcoma. For patients with isolated pulmonary metastases, metastasectomy of all pulmonary disease improves prognosis.[4] The surgical technique to best accomplish resection of pulmonary metastases in osteosarcoma has not been investigated with clinical trials and is a question open to debate. Because CT has been demonstrated to have less sensitivity for presence of pulmonary metastases than surgical exploration, some researchers believe that the surgical standard of care for osteosarcoma with isolated pulmonary metastases should be open thoracotomy with resection of all palpable pulmonary disease.[434] However, others argue a video-assisted thoracoscopic surgery approach is adequate in some cases.[435]

Recurrent Osteosarcoma

The recurrence of osteosarcoma is an unfavorable event, with subsequent outcome most influenced by the time to recurrence, burden of disease at the time of recurrence, and resectability of the recurrent disease. In a series from the COSS group,[7] 576 of an initial 1702 patients developed recurrent disease at a median time of 1.6 years (range, 0.1 to 14.3 years). EFS was 0.13 (standard error [SE], 0.01) at 5 years and 0.11 (SE, 0.02) at 10 years, with an OS of 0.23 (SE, 0.02) at 5 years and of 0.18 (SE, 0.02) at 10 years. The most important factor associated with survival was achievement of a second surgical complete remission. The ability to achieve second surgical complete remission was likely related to the number and bilaterality of pulmonary lesions, as well as pleural disruption by the pulmonary metastasis. Patients with multiple lesions, bilateral lesions, and lesions that disrupted the pleura fared less well. Chemotherapy was of limited benefit, with multiagent therapy probably more effective than single-agent therapy.

Similar results have been reported from the Rizzoli Institute[6] in a study of 175 patients. Again, achievement of a second surgical remission was key to survival and was more readily accomplished in patients with recurrence limited to the lungs (97 of 125 [75%] of those with isolated pulmonary recurrence as compared with 21 of 37 [57%] of those with other than lung metastasis). EFS was 16%, with postrelapse survival of 39% at 5 years for those who achieved a second complete surgical remission but 0% among those who did not. A longer initial relapse-free interval (>24 months) and the presence of only one or two lung metastases were favorable prognostic indicators in patients with isolated pulmonary metastases who achieved a second complete surgical remission. Chemotherapy slightly prolonged survival in those who did not achieve a second surgical complete remission and possibly in those with three or more pulmonary nodules who underwent resection. Other groups have reported comparable findings in smaller numbers of patients.[114,431,435,437] Aggressive and, if necessary, repeated thoracotomies have also been advocated by many.[438-441]

As discussed earlier (see "Determinants of Metastasis" under "Biology"), the development of pulmonary metastasis may be facilitated by the absence of FAS on the malignant cell surface. Tumor cells expressing FAS are eliminated by the lung endothelium, which constitutively expresses FASL. The metastatic potential of osteosarcoma cells in model systems has been shown to be inversely related to FAS expression, and metastatic osteosarcoma samples often lack FAS expression.[334,442,443] It was hypothesized that the administration of GM-CSF by the inhalation route may enhance FAS expression on osteosarcoma cells. A study at the Mayo Clinic in 40 patients with pulmonary metastases from a variety of malignancies has shown benefit in at least 50%.[444] Dose escalation in patients with melanoma has shown melanoma-specific T cells at the higher dosage levels of 1750 and 2000 µg administered by the inhalation route twice daily, 1 week on and 1 week off (S. Markovic, personal communication, 2008). A COG study (AOST 0221) investigated the feasibility of inhaled GM-CSF monotherapy in patients with recurrent osteosarcoma, with biologic end points including analysis of the FAS pathway and study of infiltrating dendritic cells. Metastatic nodules resected after inhaled GM-CSF did not display induction of FAS expression and had limited evidence of dendritic cell infiltrate.[379]

Chemotherapy administration via the inhalation route is one approach being considered for both recurrent and primary metastatic osteosarcoma. Advantages of inhaled delivery include the ability to circumvent first pass metabolism in the liver, decreased systemic absorption, and, consequently, decreased systemic symptoms. A phase Ib/IIa study of inhaled lipid cisplatin demonstrated this therapy to be feasible and to have minimal systemic toxicity. Activity in patients with gross pulmonary metastases was limited.[445] An ongoing phase II study is evaluating the activity of this therapy in patients with recurrent osteosarcoma limited to the lungs whose pulmonary nodules have been completely resected.

In a phase II study of the pan-kinase inhibitor sorafenib in 35 patients with recurrent osteosarcoma with measurable disease, 3 patients (8%) had a partial response according to RECIST (Response Evaluation Criteria in Solid Tumors) and progression-free survival at 4 months was 46%.[446] The mechanism of action of sorafenib in osteosarcoma is not known. Data from preclinical models suggests sorafenib inhibits angiogenesis, which is not unexpected given that sorafenib is a potent inhibitor of vascular endothelial growth factor receptors (VEGFRs).[369] This hypothesis is supported by the observation of partial responses in osteosarcoma patients enrolled on phase I trials of potent VEGFR inhibitors cediranib[447] and regorafenib.[448] Sorafenib may also function via inhibition of ERK1/ERK2 signaling.[369]

In summary, recurrent osteosarcoma carries a grave prognosis. Cure is most likely in the minority of patients who have a limited number of metastases that are completely resected, leading to a second complete surgical remission, especially if the first remission was of relatively long duration. The role of adjuvant therapy for patients with recurrent osteosarcoma is uncertain. Enrollment of such patients in clinical trials should be encouraged.

Radiation Therapy

Radiation therapy is relatively ineffective against osteosarcoma, especially when compared with the combination of adequate surgery and multiagent chemotherapy. In vitro studies comparing osteosarcoma with other human cell lines have demonstrated that osteosarcoma cells are more resistant to irradiation.[449] In addition, those osteosarcomas with loss of TP53 function would be expected to survive radiation-induced DNA damage.[208,220]

Adjuvant pulmonary radiation therapy has been compared in a randomized fashion with adjuvant VCR plus HDMTX.[450] Although outcomes were the same in patients receiving chemotherapy and those receiving pulmonary irradiation, DFS in both arms of the study was much lower (at 24%) than with the current standard approach of wide surgical resection and multiagent chemotherapy.[110] In addition, 14% of patients receiving adjuvant pulmonary irradiation experienced decreased pulmonary function. Thus adjuvant pulmonary irradiation is not recommended.

Radiation therapy has been used for local control of osteosarcoma. When radiation therapy is the only local control measure (i.e., no operation is performed), the local recurrence rate is almost three times greater than is seen with surgical resection.[450] Nevertheless, when surgical resection of the primary lesion is not an option, there may be a role for radiation therapy. Machak and colleagues[451] have reported a 5-year OS survival of 60% in 31 patients who refused surgical resection of the primary tumor and were treated instead with local irradiation and multiagent chemotherapy. Similarly, patients with osteosarcoma of the spine who had intralesional margins or no surgery tended to have a better outcome if they received local irradiation plus multiagent chemotherapy than chemotherapy alone, although the difference was not statistically significant.[452] Proton-based radiotherapy used in the setting of incomplete or no resection produced reasonable local control rates, but only 35% of patients in the series had high-grade osteosarcoma.[453] Contrasting results have been presented by Hug and associates,[454] who saw local failures in 2 of 3 patients who did not undergo surgical resection of the primary tumor but were treated with local irradiation and multiagent chemotherapy.

Preoperative irradiation, in combination with neoadjuvant multiagent chemotherapy, has been given in an attempt to increase the rate of limb salvage surgery.[455] Although this approach has resulted in a higher percentage of limb salvage procedures compared with historical controls, local complications were also increased. Given the increased rate of local complications, this approach is not recommended.

Whether postoperative irradiation is useful when inadequate surgical margins are present is controversial. There are no randomized trials comparing postoperative irradiation with observation in patients whose tumor resection specimens had marginal or intralesional surgical margins. Studies that have compared such patients with similar historical controls show an improved local control rate and OS in patients treated with local postoperative irradiation.[452,456] However, a great diversity of tumor burden is present in patients with intralesional and marginal tumor margins, and chemotherapy regimens have changed over time. Thus, comparison with historical controls might not be valid.

Samarium 153-labeled ethylenediaminetetramethylene phosphonate (^{153}Sm-EDTMP) is a pharmaceutical radioisotope that is efficiently and specifically taken up by bone. Patients with osteosarcoma bone metastases treated with ^{153}Sm-EDTMP experience a rapid decrease in pain symptoms.[457] At high doses of ^{153}Sm-EDTMP, peripheral blood stem cell rescue is required.

Complications of Therapy and Late Effects

Patients receiving osteosarcoma therapy can experience acute complications from chemotherapy and surgery. As noted, the usual initial osteosarcoma chemotherapy comprises HDMTX, Doxo, and CP. Ifosfamide and etoposide are also given in many protocols. The acute toxicities of HDMTX, Doxo, and CP combination chemotherapy with and without ifosfamide have been well documented in numerous osteosarcoma treatment protocols.[111,113,133,404,422,423] The most common acute side effects, occurring in 75% of patients, are grades 3 or 4 leukopenia and neutropenia. Significant nausea and vomiting are also common and occur in 60% to 70% of patients, particularly during Doxo-CP cycles; 20% to 30% of patients experience mucositis. A similar percentage develops significant infections. Reversible aminotransferase elevations occur in about 15% of patients, usually because of HDMTX. Renal toxicity, which occurs in 1% to 2% of patients, presents as renal insufficiency or tubular dysfunction, with accompanying electrolyte abnormalities. Renal dysfunction can be acute or chronic. Neurologic toxicity presenting as seizures, headache, or radiologic changes is rare. The rate of therapy-related mortality varies from 0% to 4%, with most protocols reporting a 1% to 2% rate of therapy-related mortality, usually caused by infection and, less frequently, by cardiotoxicity.

A potential complication of HDMTX therapy in all disease settings is renal damage from insoluble MTX metabolites. Because MTX is primarily excreted by the kidneys, renal damage can lead to delayed MTX clearance, which in turn worsens renal dysfunction and further delays MTX clearance. Delayed MTX clearance, even in the setting of adequate leucovorin rescue, can lead to severe mucositis and prolonged myelosuppression. With adequate hydration, alkalinization, and monitoring of drug levels, the incidence of severely delayed MTX clearance is low. Delayed MTX clearance can be treated with increased hydration, adjustments in leucovorin dosing, hemodialysis, or carboxypeptidase (glucarpidase), an enzyme that converts MTX to inactive metabolites that are readily excreted in the urine.[458]

Acute complications of osteosarcoma primary resection surgeries are reviewed extensively in Chapter 49, "Pediatric Surgical Oncology." Limb salvage procedures have a much higher rate of perioperative complications than amputations. In one study, 41% of limb-sparing procedures had wound complications compared with only 13% of amputations.[111] Acute complications of surgery include infection, flap necrosis, damage to the neurovascular bundle, and venous thrombosis.[111,459]

Late effects of chemotherapy in patients with osteosarcoma include cardiac dysfunction, hearing loss, secondary malignancy, and decreased fertility.[115] Guidelines regarding posttreatment monitoring for late effects and relapse are presented in Table 62-8. Many osteosarcoma protocols use a cumulative doxorubicin dosage of 450 mg/m^2. Published rates of cardiac toxicity after treatment for osteosarcoma range from 0% to 5%.[111,120,404,423] Cardiac dysfunction caused by Doxo is irreversible and can be severe enough to cause death or require transplantation. Doxo-related cardiotoxicity is more common in women and is more likely with higher cumulative Doxo dosages.[460] Younger children treated with Doxo may develop delayed cardiac failure during rapid somatic growth in adolescence, and women may similarly develop cardiac failure as a result of the increased cardiac workload presented by pregnancy. The long-term cardiac outcome of patients treated with Doxo especially at a relatively high cumulative dosage remains to be defined. Administration of dexrazoxane in conjunction with Doxo in pediatric sarcoma patients has led to preservation of left ventricular function, without any change in outcome, compared with placebo control in an initial small clinical trial.[461] Recently, dexrazoxane administration in patients receiving therapy for Hodgkin disease has been associated with an increased risk for subsequent acute myeloid leukemia and myelodysplastic syndrome.[462] It is uncertain whether these findings pertain to patients with other disease types.

Second malignancies occur at an increased rate in osteosarcoma survivors compared with the general population or patients with benign bone tumors.[463,464] The incidence of second malignancies ranges from 2% to 4%.

TABLE 62-8 Typical Monitoring after Completion of Therapy*

Routine Monitoring for Tumor Recurrence (also imaging for symptoms, as indicated)	
First Year	
Primary site	Plain radiograph every 3 months
Site(s) of bone metastases	Plain radiograph film every 3 months
Chest	Chest CT every 3 months
Second Year	
Primary site	Plain radiograph every 6 months
Site(s) of bone metastases	Plain radiograph every 6 months
Chest	Chest CT every 6 months
Third Year	
Primary site	Plain radiograph every 6 months
Site(s) of bone metastases	Plain radiograph every 6 months
Chest	Chest radiograph every 6 months
Fourth and Fifth Years	
Primary site	Plain radiograph every 12 months
Site(s) of bone metastases	Plain radiograph every 12 months
Chest	Chest radiograph every 6 months
Sixth to Tenth Years	
Primary site	Plain radiograph every 12 months
Site(s) of bone metastases	Plain radiograph every 12 months
Chest	Chest radiograph every 12 months
Monitoring for Late Effects of Chemotherapy	
Cardiac	Echocardiogram every 12 months for 2-3 years then at the time of pubertal growth spurt and pregnancy
Nephrotoxicity	Monitor electrolytes, blood urea nitrogen, creatinine every 12 months
Ototoxicity	Audiology at end of therapy
Secondary malignancy	Complete blood cell count every 12 months
Fertility	Semen analysis offered to postpubertal males
All	Physical examination every 3 months × 1 year, every 6 months until 5 years after completion of therapy then yearly

CT, Computed tomography.

*Recommendations for posttreatment surveillance vary. For further reading see references 475 to 477.

Because a number of genetic cancer syndromes increase osteosarcoma risk, it is difficult to determine whether second malignancies are caused by an underlying genetic predisposition or a complication of osteosarcoma therapy. Certainly some of the osteosarcoma survivors who develop a second malignancy have no family history of cancer. No particular type of secondary malignancy predominates.

Ototoxicity as a result of osteosarcoma therapy is predominantly caused by CP. In some patients, aminoglycoside treatment of infectious complications of chemotherapy may be a contributing factor. Mild ototoxicity, which does not involve the frequencies of audible speech, is relatively common. Significant ototoxicity involving the audible speech frequencies is rare, reported in 1% or fewer patients.[465] Amifostine, administered concurrently with CP, has been tested in a small group of pediatric osteosarcoma patients. Compared with untreated controls, patients receiving amifostine had less severe myelosuppression but the incidence of renal and ototoxicity was not decreased by amifostine therapy. Amifostine was emetogenic but was otherwise well tolerated.[466]

Azoospermia is known to be caused by alkylating agents and is common in osteosarcoma patients treated with ifosfamide. Azoospermia has also been seen in patients who were treated with HDMTX, Doxo, and CP; and it is likely that this is chemotherapy related.[467] Data on female infertility after osteosarcoma therapy are limited. In one study, 6% of female patients treated with HDMTX, Doxo, and CP plus ifosfamide had early menopause.[468]

Long-term orthopedic complications, which depend on the type of surgical resection performed, are discussed further in Chapter 49, “Pediatric Surgical Oncology.” Patients who have limb-sparing operations are more likely to have late orthopedic complications. Most late complications are caused by endoprosthesis or allograft failure, although late infections also occur.[459] Thirty percent of endoprostheses will require surgical revision or replacement by 10 years after the initial surgery.[469] Other problems that arise in patients undergoing limb-sparing surgery include poor joint mobility and leg-length discrepancy, both of which can impair limb function. Although limb-sparing procedures have a higher complication rate, the functional outcome is superior when assessed by oxygen consumption during walking. Functionally, rotationplasty is equivalent to a below-knee amputation.[459] In long-term follow-up studies, quality of life did not differ in those who had an amputation when compared with those who underwent a limb-sparing procedure. Poorer lower limb function does have an adverse impact on quality of life, and failure of a limb-sparing procedure had an impact on body image.[470] Compared with survivors of other childhood cancers and their siblings, survivors of osteosarcoma have greater activity limitations.[471,472] Despite these limitations, those who are long-term survivors after osteosarcoma appear to have similar social and occupational outcomes as their siblings.[473]

CONCLUSION AND FUTURE DIRECTIONS

Osteosarcoma treatment and prognosis have not changed significantly during the past 2 decades. The standard basic chemotherapy for localized osteosarcoma—Doxo, CP, and HDMTX—has remained the same. Consequently, outcomes in patients with localized osteosarcoma are similar today to outcomes 20 years ago. New therapies, particularly ifosfamide and etoposide, have been used for patients with metastatic and recurrent disease, and there are early indications that this may result in a slight improvement in outcome. In contrast, surgical approaches have changed significantly over the past 20 years. Previously, amputations were common; currently, many patients have limb-sparing surgeries. In addition, there has been increasing recognition of the ability to increase survival via complete resection of pulmonary metastases.

This relatively slow rate of progress in treatment of osteosarcoma is partly the result of the biologic complexity of the disease. There have been a number of biologic insights over the past 2 decades, but none has revealed obvious drug targets that are of central relevance in a large proportion of osteosarcomas. An additional factor slowing the rate of progress in osteosarcoma is the small patient population available for clinical studies.

Several ongoing clinical studies should provide important clinical insights in the next 5 to 10 years. It is hoped the results of the international cooperative study EURAMOS1 will determine whether the postoperative addition of ifosfamide and etoposide improves the EFS of patients with a poor response to neoadjuvant chemotherapy.

Identification of new therapeutic agents with activity in osteosarcoma is a major research priority. Several novel agents are likely to be evaluated in phase II clinical trials in osteosarcoma in the next several years. The Sarcoma Alliance for Research through Collaboration (SARC) is studying an SRC inhibitor in patients with metastatic osteosarcoma. Phase II studies of the microtubule inhibitor eribulin, of the anti-GD2 antibody CH14.18, and of the RANKL antibody denosumab have been proposed by the COG.[474]

Breakthroughs in the understanding of osteosarcoma biology are likely in the next 10 years as the number and sophistication of tools and techniques for biomedical research continue to increase. For example, improved transgenic mouse models of osteosarcoma are likely to be developed, and these models will facilitate basic and applied studies. Results of comprehensive next-generation sequencing studies are expected at the time of publication. Genomic and proteomic techniques requiring minimal amounts of tumor tissue will continue to facilitate the study of human osteosarcoma samples, which are in limited supply. It is hoped the combination of these new techniques, with the proliferation of new drug compounds and the recently established international collaboration for clinical studies, will lead to significant advances in osteosarcoma in the near future.

CONCLUSIONS

Germ cell tumor (GCT) is the designation given to neoplasms arising from the cells of the germline—the cells that are destined to become either the egg or the sperm. A number of unique features of these tumors including their bimodal and wide age distribution, remarkable phenotypic diversity, and varying biologic behavior make GCTs a particular challenge for the surgeon, pathologist, and oncologist. Successful treatment regimens developed over the last several decades have focused current clinical research on ways to maintain efficacy and minimize toxicity for most patients and intensify treatment for patients who fail first-line therapy. Recent advances in understanding the underlying aberrations in germline development shed light on the genesis of these tumors and may provide insight into new avenues for treatment.

DEVELOPMENT OF THE GERMLINE

The pathogenesis of GCTs can best be understood through an analysis of the mechanisms of germline development.[1] The role of the germ cell is to ensure the continuation of a species by producing the gametes, cells that will give rise to the next generation. Reflecting this unique role, germ cells are set aside from somatic cells very early in development. In humans, germ cells arise in an extraembryonic position and must migrate to the site at which the gonads will form. The pluripotency of germ cells is reflected in the wide histopathologic diversity of GCTs.

Specification of Primordial Germ Cells

Much of what is known about early molecular events in the mammalian germline comes from examination of germ-cell development in the mouse.[2-5] Similar molecular mechanisms of germ cell development appear to operate in humans, based on studies of human embryos and human embryonic stem cells differentiating into germ cells in vitro.[6-10] Development of the germline begins at the time of blastocyst implantation, when the extraembryonic ectoderm and the visceral endoderm send signals to cells in the proximal epiblast, also known as the *embryonic ectoderm* (Fig. 63-1). The major inductive signals are the bone morphogenetic proteins (BMPs), which are members of the transforming growth factor β (TGF-β) superfamily.[11-14] In response to BMPs, some of the epiblast cells begin to express the marker *fragilis*,

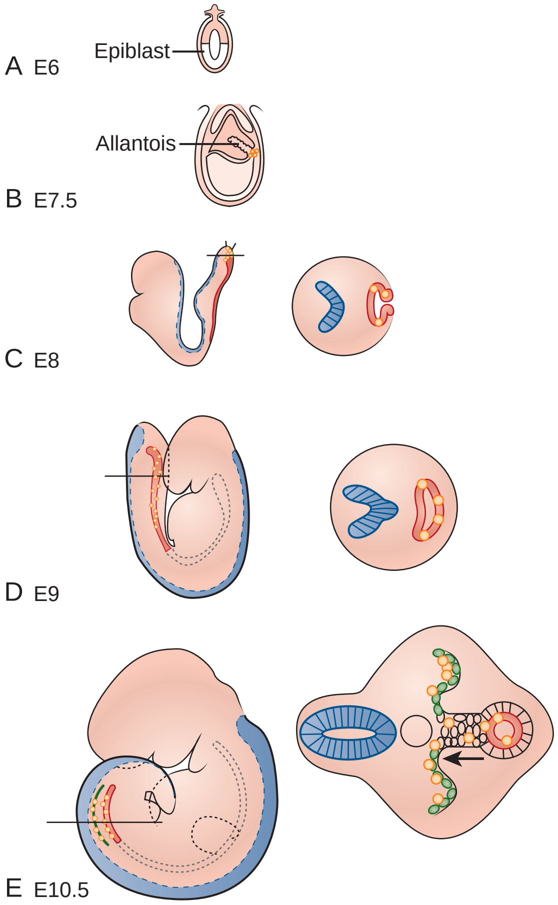

Figure 63-1 Development and migration of PGCs. Stages of embryonic development and primordial germ cell (PGC) migration in the mouse. **A,** At E6 the epiblast *(white)* and extraembryonic tissue *(gray)* are discernable. **B,** By E7.5 the allantois has developed and the PGCs *(yellow)* appear. **C,** At E8 the neural tube *(blue)* and hindgut[70] can are visible. In cross-section *(right side)*, the PGCs can be seen colonizing the hindgut. **D,** At E9 the embryo has turned and the posterior section is to the left; the PGCs are migrating through the hindgut. **E,** At E10.5 the PGCs begin exiting the hindgut and migrate through the dorsal mesentery *(white cells)* to enter the genital ridges *(green)*. The equivalent stages of human embryonic development are: **A,** Weeks 1 and 2; **B,** Week 2.5; **C,** Week 3; **D,** Week 4; **E,** Week 5. *(Modified from Starz-Gaiano M, Lehmann R: Moving towards the next generation.* Mech Dev *105:5–18, 2001.)*

signaling their competence to become germ cells.[2,15] Of these *fragilis*-expressing cells, a few begin to express the transcriptional repressor *Blimp1/Prdm1*.[16] These cells, in which expression of somatic genes such as *Hoxb1, T/Brachyury,* and *Snail* is repressed, will become the primordial germ cells (PGCs). Unlike other epiblast-derived cells, PGCs regain or maintain expression of certain genes associated with pluripotency such as *STELLA, OCT3/4,* and *NANOG*.[2,17-25] Certain pluripotency genes can be reactivated in GCTs and may contribute to malignant potential; for example, *NANOG* and *OCT3/4* have been used as sensitive markers of malignant germ cells in studies of GCTs.[26-30] In humans, PGCs can be identified in the wall of the yolk sac by their intrinsic alkaline phosphatase activity beginning at about day 24. The PGCs begin to proliferate as they migrate out of the yolk sac into the embryo.[31]

Primordial Germ Cell Migration

In humans, as in many other organisms, the PGCs arise in an extraembryonic location, distant from the eventual site at which the gonad will form. This physical separation may serve to insulate the germ cells from various proliferation and differentiation signals in the developing embryo or to enforce a quality control by selecting for healthy PGCs capable of successfully navigating to the developing gonad. Proper PGC migration is critical to the survival of the germ cells and formation of the gonad, and failure of this migration can result in ectopic germ cells. Persistence and malignant transformation of these ectopic germ cells is one possible mechanism by which extragonadal GCTs are thought to arise.[32]

Toward the end of gastrulation, morphogenetic movements in the developing embryo bring the PGCs in proximity to the hindgut.[31] Invading the endoderm, the PGCs colonize the hindgut and begin vigorous, apparently random migratory movements, remaining confined to the gut. The receptor tyrosine kinase c-kit, expressed in PGCs, and its ligand, Steel, expressed in somatic cells, are required for the colonization of the hindgut and for the survival and migration of PGCs within the gut.[33-36] Wylie and co-workers have shown that in mice, PGCs deficient in c-kit signaling undergo apoptosis through the action of the p53-target gene, *Bax*.[36-39] At 5 to 6 weeks after fertilization, the PGCs upregulate expression of the adhesion factor E-cadherin[40] and exit the hindgut on the dorsal side to begin colonization of the genital ridge primordia. The genital ridges are bilateral swellings of mesenchyme covered by coelomic epithelium and situated on either side of the dorsal aorta on the posterior wall of the embryo in the lower thoracic and lumbar regions.[41] The genital ridges appear to attract the PGCs because of their expression of stromal cell–derived factor 1 (SDF-1, or CXCL12), which is a ligand for the chemokine receptor CXCR4, which is expressed in the PGCs.[42,43] As the PGCs exit the hindgut, they divide into two lateral streams to colonize the genital ridges. PGCs that fail to colonize the ridges and remain in the midline are eliminated by apoptosis, as the midline cells downregulate expression of Steel.[39] Once they have entered the genital ridges, PGCs become much less motile but continue several more rounds of division. This proliferation is dependent on continued Steel/c-kit signaling.[31,38,39,42,44]

Erasure of Imprinting

Imprinting refers to the epigenetic modification of certain genes (typically by cytosine methylation) such that only the maternal or paternal allele of the gene is expressed.[45-47] Lineage-specific patterns of imprinting are established in different tissues, including the germline, around the time of gastrulation.[46,48] Upon entering the gonadal ridges, however, PGCs actively erase these genomic methylation patterns. This erasure is necessary in order to allow the maternal and paternal imprinting patterns to be established in the oocytes and sperm, respectively. Imprinting is reestablished in sex-specific patterns during gonadogenesis.[49-51] GCTs exhibit partial or total erasure of imprinting, implying their origin from early germ cells.[1]

Gonadogenesis

Beginning shortly before the arrival of the PGCs in the genital ridges, the coelomic epithelium begins to proliferate and invade the underlying mesenchyme, forming the primitive sex cords. Migrating PGCs entering the gonad are surrounded by the cords. At this early stage, the appearance of the developing gonad is identical in males and females, and the tissue is referred to as the *indifferent gonad*. Subsequently, changes occur in both the germ cells and the gonadal somatic cells according to the genetic sex of the embryo. In genetic males, sex determination occurs under the influence of the testis-determining *SRY* gene on the Y chromosome.[52,53] After the initial rounds of cell division, male germ cells enter a mitotic arrest that persists until after birth.[14] In males, the primitive sex cords proliferate and penetrate deeper into the mesenchyme, forming the testis or medullary cords, which connect proximally to form the rete testis. By the fourth month of development, the cords consist of germ cells and the supporting Sertoli cells, which are derived from the surface epithelium of the genital ridge. The cords remain solid until puberty, when they form lumens to become seminiferous tubules. By the eighth week of development the mesenchyme of the gonadal ridge gives rise in males to Leydig cells, which secrete testosterone. Secretion of antimüllerian hormone by the Sertoli cells and testosterone by the Leydig cells leads in males to degeneration of the paramesonephric ducts and the development of the mesonephric ducts into the vas deferens and epididymis. Testosterone is also necessary for male differentiation of the external genitalia.

Female gonadal development proceeds along different lines. In the absence of the Y chromosome, the sex cords initially degenerate and are replaced by a new set of cortical sex cords derived from the surface epithelium. By the fourth month the cortical sex cords have become isolated clusters with each cluster surrounding a single germ cell. In females the primitive germ cells, called *oogonia,* continue rapid proliferation, reaching maximal numbers by the seventh month. After that point, most of the oogonia degenerate; the remaining cells, now called *primary oocytes,* enter meiosis and arrest at the diplotene stage of the first meiotic prophase. Granulosa cells (derived from the surface epithelium) and thecal cells (derived from the mesenchyme) together form the follicle cells that surround each primary oocyte. Beginning at adolescence, groups of oocytes periodically resume meiosis. In females, the paramesonephric (müllerian) ducts develop into the oviducts, uterus, cervix, and upper part of the vagina. The mesonephric ducts degenerate.

In summary, development of the germline requires the proper specification of PGCs and their migration through the embryo to the gonadal ridges, where the gonads are formed through interactions of the germ cells with somatic cells. Concomitant with this process, the inherited pattern of genomic imprinting is erased, and a new, sex-specific pattern is formed. The complex process of gonadal organogenesis is subject to both genetic and environmental influences. Abnormal development of the gonads during the embryonic and fetal periods leads to defects such as cryptorchidism and gonadal dysgenesis, which are strongly associated with the risk of developing GCTs.

HISTOPATHOLOGY OF GERM CELL TUMORS

GCTs are a heterogeneous group of neoplasms with a wide variety of histopathologic features. This variety reflects the pluripotent nature of the PGCs from which GCTs arise.[1,54] Adding to the complexity of this tumor type, GCTs with apparently similar histopathology can have very different biologic behaviors when presenting at different ages or anatomic sites. The five major histologic subtypes of GCTs are teratoma, yolk sac tumor (YST), germinoma, embryonal carcinoma, and choriocarcinoma. The World Health Organization (WHO) classification of GCTs is presented in Boxes 63-1 and 63-2.

Overview of Testicular Germ Cell Tumors

Before puberty in infants and children, teratoma and/or YST account for the vast majority of GCTs.[55-57] *Seminoma* (the term used for a testicular germinoma), embryonal carcinoma, and choriocarcinoma are very rare in this age group. GCTs of the prepubertal testis differ from their adult counterparts not only in the distribution of histologic subtypes, but also in their spectrum of cytogenetic abnormalities. After the early peak of testicular YST and teratoma in the 0-to-4–years age group, testicular tumors are relatively rare until the onset of puberty. Between ages 10 and 40 years, there is a second peak in testicular tumor incidence, comprised of seminoma and nonseminomas (including embryonal carcinoma, teratoma, YST, and choriocarcinoma). Postpubertal tumors demonstrate a wider array of histopathologic differentiation than do the GCTs of the prepubertal testis. Moreover, adolescent and adult GCTs share a common precursor cell of origin (the carcinoma in situ [CIS] or intratubular germ cell neoplasia, unclassified [IGCNU]), as well as characteristic cytogenetic abnormalities including the near-universal presence of amplifications of chromosome 12p. These histopathologic and molecular cytogenetic differences have lent support to the hypothesis that different pathogenic mechanisms underlie juvenile and adult testicular GCTs.[58-60]

Overview of Ovarian Germ Cell Tumors

In neonates and infants, the most common ovarian lesions are ovarian cysts.[61] Cysts can occur any time from late gestational stages onwards, and they occur at a greater rate in babies of mothers with diabetes, preeclampsia, and Rh immunization. Ovarian cysts in children often resolve

GERM CELL TUMORS

- Dysgerminoma
- Yolk Sac Tumor
  - Polyvesicular vitelline tumor
  - Glandular variant
  - Hepatoid variant
- Embryonal carcinoma
- Polyembryoma
- Nongestational choriocarcinoma
- Mixed germ cell tumor

BIPHASIC OR TRIPHASIC TERATOMA

- Immature teratoma
- Mature teratoma
  - Solid
  - Cystic
    - Dermoid cyst
  - Fetiform teratoma

MONODERMAL TERATOMA AND SOMATIC-TYPE TUMORS ASSOCIATED WITH DERMOID CYSTS

- Thyroid (Struma ovarii)
- Carcinoid
- Neuroectodermal
- Carcinoma
- Melanocytic
- Sarcoma
- Sebaceous tumors

GERM CELL SEX CORD-STROMAL TUMORS

- Gonadoblastoma
  - Variant with malignant germ cell tumor
- Mixed germ cell sex cord-stromal tumor
  - Variant with malignant germ cell tumor

SEX CORD-STROMAL TUMORS

- Granulosa-stromal cell tumor
  - Granulosa cell tumor
    - Adult type granulosa cell tumor
    - Juvenile type granulosa cell tumor
- Tumors of the thecoma/fibroma group
  - Thecoma
  - Fibroma
- Sertoli-stromal cell tumors
  - Sertoli cell tumor
  - Stromal-Leydig cell tumor
- Sex cord-stromal tumors of mixed or unclassified types
- Steroid-cell tumors
  - Leydig cell tumor
  - Steroid cell tumor, not otherwise specified

spontaneously without intervention.[62] GCTs account for 75% of ovarian tumors in the first 2 decades of life and up to 90% of ovarian tumors in premenarchal girls. The majority of these (95%) are benign, mature teratomas, mostly commonly "desmoid" tumors.[63] Five percent of ovarian GCTs are malignant; these include dysgerminomas, immature teratomas, mature teratomas with somatic malignancies, YSTs, choriocarcinoma, embryonal carcinoma, polyembryoma, and mixed GCTs. Finally, gonadoblastoma is a mixed germ cell–sex cord stromal tumor occurring in cases of mixed gonadal dysgenesis with ambiguous genitalia, or 45,X Turner syndrome with Y chromosome material.[64-67] The histopathology of ovarian GCT types is similar to that of their testicular counterparts. After the third decade of life, ovarian GCTs occur rarely, and carcinomas derived from the coelomic epithelial covering of the ovary are much more common.[68]

Intratubular Germ Cell Neoplasia, Unclassified

IGCNU,[69] also called *testicular CIS,*[70] is considered the precursor for all invasive testicular GCTs (TGCTs) of postpubertal males[59,71-76] except spermatocytic seminoma.[77] According to one source, if left untreated IGCNU has a up to a 50% probability of progressing to invasive TGCT, either seminoma or nonseminoma, within 5 years.[74] Nonseminomas can be composed of embryonal carcinoma (the stem cell component), teratoma (somatic differentiation), and YST and choriocarcinoma (extraembryonic lineages). In IGCNU, germ cells with abundant vacuolated cytoplasm; large, irregular nuclei; and prominent nucleoli are found within the seminiferous tubules, showing similarities to PGCs and early gonocytes.[69] IGCNU is found in 1% of cases of male infertility and in 2% to 4% of cryptorchid testes in adults.[69,73,76,78-81] In men with a TGCT, the prevalence of IGCNU is about 80% in the ipsilateral testis (range, 63% to 99%],[79,82] predominantly in men with nonseminomas,[83] and 5% in the contralateral testis.[71,84,85] Various markers such as placental alkaline phosphatase (PLAP), c-kit, transcription factor AP-2γ, OCT3/4 (POU5F1), and testis-specific protein Y-encoded (TSPY) have been extensively used for immunohistochemical detection of IGCNU.[26,30,79,86-93] All these markers are also found in PGCs and/or gonocytes, which supports the model that IGCNU derives from PGCs or gonocytes.[1,30,94]

Whether an identifiable precursor lesion exists for GCTs of children is much less clear. In prepubertal children, the incidence of IGCNU appears to be very low,[58,95,96] although several cases have been reported.[94,97-99] These data must be interpreted with caution, however, because of the difficulty of distinguishing IGCNU in the developing gonad, in which primitive germ cells normally express markers such as *OCT3/4* and *c-KIT*.[94] The precursor lesion for the teratomas and YSTs of neonates and infants is yet to be identified. These pediatric tumors show partially erased imprinting, suggesting that the cell of origin is most likely a germ cell at an earlier development stage than that of IGCNU.[100-102]

IGCNU has been reported in a high percentage of gonadal biopsy specimens from children with disorders of sexual development (DSDs) who are at risk for the development of germ cell malignancies.[103,104] These disorders include gonadal dysgenesis,[105,106] partial androgen insensitivity syndrome (AIS),[107] and less often, complete AIS.[66,108-110] Development of these tumors in patients with DSDs is linked to the presence of a specific fragment of the Y chromosome, known as the *GBY region.*[29,93,111-114] For these patients with an increased risk of germ cell malignancy, prophylactic gonadectomy is often indicated.[103,115] However, overdiagnosis of IGCNU is possible

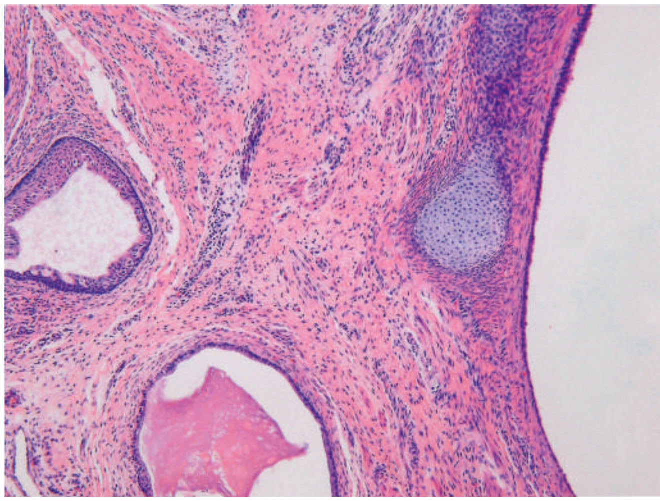

Figure 63-2 Mature teratoma. Low-power view showing cystic tumor with areas of cartilaginous differentiation.

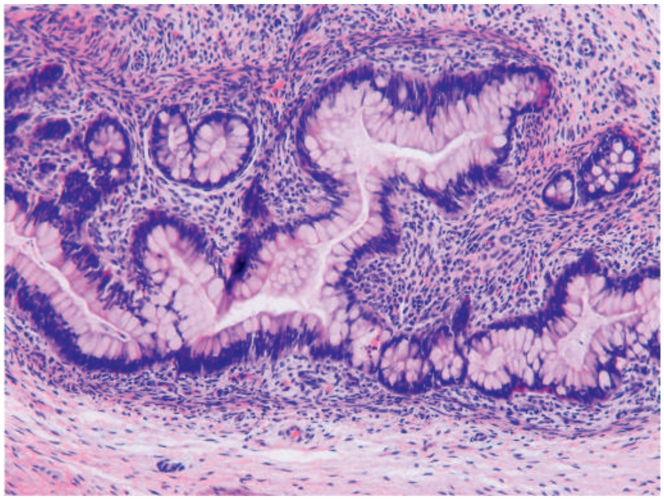

Figure 63-3 Mature teratoma with glandular differentiation.

in this setting because of the common maturation delay of germ cells in patients with DSDs, resulting in retained presence of *c-kit*-positive germ cells.[21,116,117] Therefore careful examination of the distribution pattern of *OCT3/4*-positive cells and their position within the seminiferous tubule are essential to making the diagnosis of IGCNU.[66,110,116]

TERATOMA

Histopathology of Teratoma

Teratomas are tumors composed of multiple tissues that are normally foreign to, and able to proliferate in excess of, the site in which they occur.[118] In the usual definition of *teratoma,* tissue elements of all three germ layers (endoderm, mesoderm, and ectoderm) are present; however, teratomas also occur in which only one or two of the germ layers are present (referred to as *monodermal* or *bidermal teratomas,* respectively). The clinical and biologic behavior of teratomas varies significantly with differing anatomic location, degree of maturity of the tumor tissue, and age of onset. Grossly, teratomas are nodular and heterogeneous with solid and cystic areas depending on the types of differentiated tissue present. Cartilage, bone, hair, and pigmented areas may be recognizable (Fig. 63-2). At the histopathologic level, ectodermal derivatives such as neuroepithelium, skin, and hair are the most common tissues in teratomas of infants and children. However, practically any tissue type can be seen, including muscle, bone, cartilage, and well-differentiated glands (Fig. 63-3).

Mature teratomas are typically cystic and contain differentiated adult-type tissue from one or more of the germ layers. The term *dermoid cyst* refers to the common finding in mature teratomas of tissue resembling the adult epidermis and its appendages. Immature teratomas are those in which embryonal-appearing tissue is present, typically in the form of neuroepithelial rosettes and tubules and often mixed with mature tissue (Fig. 63-4). A loose, myxoid stroma of immature mesenchyme with focal differentiation into osteoid, fat, cartilage, and rhabdomyoblasts may be present.[119] Hypercellularity, increased mitotic index and nuclear atypia can be present. The prognostic significance of these findings is different for ovarian and testicular teratomas,[56] and these are discussed separately in the next sections.

Testicular Teratoma

Testicular Teratoma in Infants and Children

In most series, testicular teratoma is the second most common GCT of the prepubertal testis, representing about 35% of GCTs.[56,60,120-123] However, the actual incidence may be higher, because prepubertal testicular teratomas are uniformly benign and thus may be underreported to tumor registries.[122-125] Histologically, 85% of prepubertal testicular teratomas are mature, and 15% are immature. Unlike the case of ovarian teratomas, the

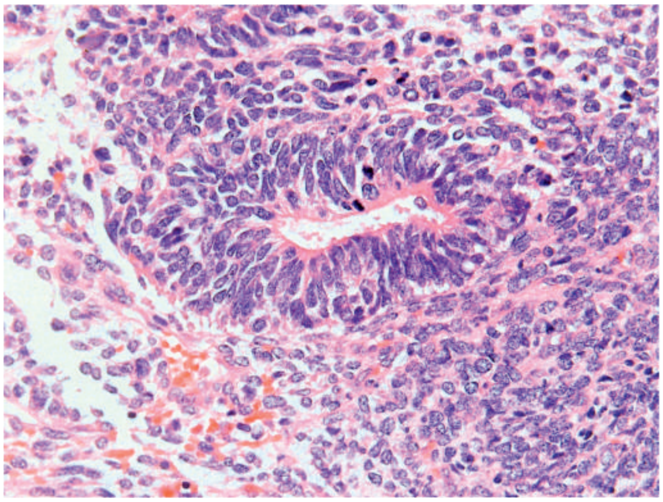

Figure 63-4 Immature teratoma. Immature teratomas are graded according to their content of primitive neuroepithelium. In this high-power view, the rosette formation characteristic of these tumors can be seen.

degree of histologic immaturity of childhood testicular teratoma does not carry prognostic significance. In this age group, pure testicular teratomas lack metastatic potential and have not been found to recur after surgical removal of the tumor.[56,126-129] A review of cases of immature teratoma from Pediatric Oncology Group (POG)/Children's Cancer Study Group (CCG) protocols concluded that the presence of microscopic foci of YST, rather than the grade of immature teratoma, is the only valid predictor of recurrence in pediatric immature teratoma at any site.[130] The benign nature of these tumors has permitted the widespread use of testis-sparing enucleation surgery for prepubertal testicular teratomas.[58,124,131-133] In agreement with the benign clinical behavior of pure teratomas of the prepubertal testis, these tumors display normal karyotypes and normal results from comparative genomic hybridization (CGH).[123,134,135] Epidermoid cysts are rare tumors in the prepubertal testis and are most likely monodermal teratomas showing ectodermal differentiation.[63,124,136,137] These tumors, which have a characteristic ultrasonographic appearance, are hormonally inactive and do not produce α-fetoprotein (AFP);[124] as with other teratomas of the prepubertal testis, they are managed conservatively with testis-sparing surgery.[124,136,138] In the prepubertal testis, the seminiferous tubules surrounding the teratoma may contain germ cells with atypical features such as enlarged nuclei. However, these features are distinct from the seminoma-like changes of IGCNU, and do not signify malignant transformation of the germ cells.[139,140]

Testicular Teratoma in Adolescents and Adults

Teratoma occurs as a component of 50% of mixed nonseminomas in the postpubertal testis. Pure teratoma is rare, accounting for only 2% to 3% of postpubertal TGCTs.[141,142] Testicular teratomas in adolescents and adults may spread, giving rise to teratomatous and nonteratomatous metastases.[55,69,133] Furthermore, adult testicular teratomas typically are associated with IGCNU and exhibit characteristic cytogenetic abnormalities such as isochromosome 12p that are also found in seminomas and in other types of nonseminomatous TGCTs. Based on these findings, Ulbright proposed that teratomas in the adult testis arise from a germ cell that has already undergone malignant transformation; thus the histogenesis of adult teratoma is distinct from that of teratomas arising in the ovary or the prepubertal testis.[133,143] Postpubertal teratomas may contain syncytiotrophoblastic giant cells, and patients with teratoma may have gynecomastia[144] or elevated serum β-human chorionic gonadotropin (β-HCG) or AFP.[145,146]

Ovarian Teratoma

Teratoma is the most common GCT of the ovary, comprising more than 95% of all ovarian GCTs.[63] Ovarian teratomas differ in important ways from testicular teratomas. Teratomas in the prepubertal testis are uniformly benign. In adolescents and adults, testicular teratomas are nearly always malignant and occur as a component of mixed malignant GCTs (MGCTs), the exception being dermoid cysts of the testis. In the ovary, in contrast, the phenotype of teratomas does not vary as strikingly by age, and ovarian teratomas are usually pure tumors.[147,148] The great majority of ovarian tumors are mature, benign tumors (often referred to as *dermoid cyst* or *mature cystic teratoma*).[133,143,149,150] Less than 5% of ovarian teratomas are malignant; these are discussed separately in the following sections.

Benign, Mature Ovarian Teratoma

Mature ovarian teratomas are diploid, cytogenetically normal tumors.[123,151-154] This contrasts to postpubertal testicular teratomas, which are aneuploid and demonstrate cytogenetic abnormalities such as i12p. Interestingly, when polymorphic molecular markers are assayed, a high percentage of mature ovarian teratomas show a homozygous pattern, indicating that these tumors can arise from a germ cell that has completed meiosis I but not meiosis II.[107,134,151,155-159] Mature ovarian teratomas are usually cystic, though solid tumors can occur, especially in the first two decades.[160,161] Other characteristics of mature ovarian teratomas include a well-ordered, "organoid" appearance to the differentiated tissues within the teratoma, and the absence of cytologic atypia.[162] Mature ovarian teratomas are uniformly benign, except in the rare case of postteratomatous "malignant degeneration" of a dermoid cyst.[133,162,163]

Malignant Ovarian Teratoma

In children, immature teratoma is the most common type of malignant ovarian teratoma. Also in this category are other tumors that are rare in children, such as monodermal teratomas with malignant elements (e.g., papillary thyroid carcinoma in struma ovarii), dermoid cysts with malignant degeneration, and the rare case of mixed malignant ovarian GCT (MOGCT) with a teratoma component.

Immature Teratoma

The term *immature teratoma* refers to teratomas containing immature-appearing tissues, principally neuroepithelium.[164] Additionally, foci of mitotically active glia may be present. A grading system has been developed for immature teratomas based on the amount of neuroepithelial tissue present.[119,165] Mature teratomas containing only fully differentiated tissue are considered grade 0, and immature teratomas range from grade 1 (comprised of less than 10% immature neuroepithelium) to grade 3 (more than 50% immature neuroepithelium present). A two-component grading system (low grade and high grade) has also been proposed and shown to have improved reproducibility.[166] In adult ovarian teratomas, the finding of grade 2 or 3 immature teratoma predicts the likelihood of metastasis and confers a worse prognosis.[119,160,166,167] In children, however, it is not clear that the same relationship of grade to outcome of immature teratomas holds true. A POG study concluded that surgery alone was curative in children and adolescents with stage I immature teratomas of any grade and that chemotherapy should be reserved for cases of relapse.[130,168]

Immature teratomas may be associated with implants of glial tissue on the peritoneum, known as *gliomatosis* *peritonei*.[169-171] If the implants are composed solely of mature tissues, the presence of gliomatosis peritonei does not "upstage" the patient.[172,173] Interestingly, data suggest that the implants arise from metaplastic transformation of pluripotent müllerian stem cells in the peritoneum or underlying mesenchyme, rather than representing metastasis of the teratoma tissue.[174-176]

Monodermal Teratomas

Monodermal teratomas consist largely or exclusively of a single type of tissue, such as thyroid, carcinoid, and neuroectodermal tissues.[63,177-180] Monodermal teratomas with neuroectodermal differentiation include indolent types such as ependymoma and poorly differentiated forms such primitive neuroectodermal tumor (PNET), as well as anaplastic tumors resembling glioblastoma.[123,181-185] These tumors are rare in children.

Teratoma with Malignant Transformation

Teratoma with malignant transformation makes up 0.2% to 1.4% of mature cystic tumors of the ovary.[133,163,186] In these tumors, more commonly seen in older women, somatic-type malignancies are seen among the individual tissues in the teratoma. Squamous cell carcinomas are the most common tumor type,[187,188] but others including melanoma, adenocarcinoma, small cell carcinoma, sarcomas (including PNET), and malignant glioma may also occur.[133,162]

YOLK SAC TUMOR

Histopathology of Yolk Sac Tumor

YST is the most common malignant GCT in infancy and childhood.[56,57,118,122,189] The differentiation of the tumor cells is predominantly along endodermal lines and can take the form of both intraembryonic endodermal derivatives, such as primitive gut and liver, and extraembryonic structures such as allantois and yolk sac. There are many synonyms for YST, including *orchioblastoma, Teilum's tumor,* and *clear cell adenocarcinoma*. Although *endodermal sinus tumor* is commonly in use as a synonym for YST, some consider the term problematic, because the endodermal sinus is not a component of normal human embryogenesis.[190] In macroscopic appearance, YSTs are yellowish, with multiple cysts and areas of hemorrhage, necrosis, and liquefaction.[162] Microscopically, YSTs display a loose, myxoid stroma containing a reticulated pattern of microcystic spaces (Fig. 63-5). The cysts are lined by a flattened, periodic acid-Schiff (PAS)–positive, diastase-resistant epithelium. About 20% of YSTs exhibit characteristic Schiller-Duval bodies (a clustering of cells around a small, central blood vessel) (see Fig. 63-5). In addition to the microcystic/reticular pattern, several variant histologies of YST are described, including the solid, polyvesicular, and parietal types (corresponding to primitive endoderm and extraembryonic structures such as the allantois and yolk sac) and the glandular and hepatic types (corresponding to the intraembryonic endodermal derivatives, primitive lung and liver).

YSTs are typically cytokeratin-positive, which can help differentiate the solid YST variant from germinomas.[162]

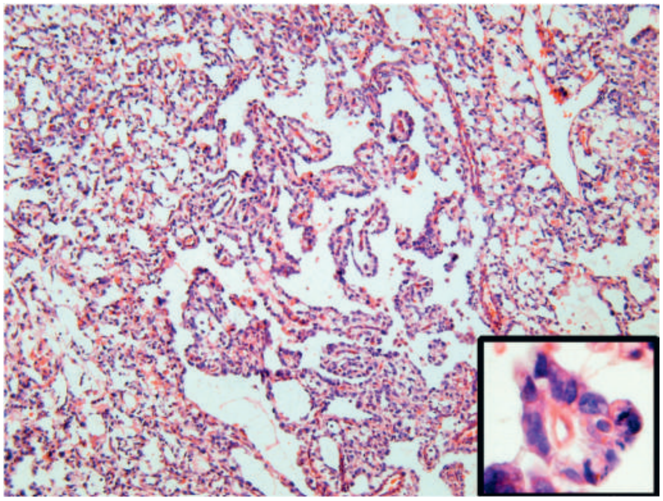

Figure 63-5 YST. A loose, myxoid stroma is filled with a labyrinthine network of cysts lined by clear, flattened epithelial cells. *Inset,* Schiller-Duval body.

Alpha-fetoprotein (AFP) expression is characteristic of these tumors, and AFP is a valuable tumor marker. Neonates and infants have high physiologic levels of AFP in serum, which can confound the use of serum AFP levels for diagnosis of YST or for monitoring therapy. Tables of normal serum AFP levels in neonates and infants have been published (Fig. 63-6).[191-193] In addition, at least 70% of YSTs have detectable AFP expression by immunohistochemical assays.[194-198]

Testicular Yolk Sac Tumor

Testicular Yolk Sac Tumor in Infants and Children

YST[199] is the most common malignant GCT in infants and children, comprising approximately 65% of prepubertal testicular GCTs.[121,200] YST is most common in males aged 0 to 2 years and can occur in pure form or as a malignant component of teratoma.[56] Histologically, prepubertal YSTs show the same spectrum of patterns as their adult counterparts: pseudopapillary, reticular, polyvesicular vitelline, and solid, with the pseudopapillary pattern being most common in children.[201] IGCNU is not a feature of childhood YST, and it is unlikely that P53 mutations play a role in pathogenesis.[95,96,135] Unlike childhood teratomas, YSTs in children are aneuploid, with characteristic, nonrandom chromosomal abnormalities including gains at 3p and losses at 1p and 6q.[135,202,203] Immunohistochemistry detects AFP expression in more than 90% of YSTs, and in most cases the serum AFP level is also elevated.[56,195,198,204-208]

Testicular Yolk Sac Tumor in Adolescents and Adults

YST in the adolescent and adult testis is extremely rare in the pure form but occurs in approximately 40% of mixed TGCTs.[209] In one series of primary mediastinal GCTs, YST was present in nearly 50% of the tumors.[210] As in childhood YST, hematogenous metastases are common, especially to the liver. The majority of tumors

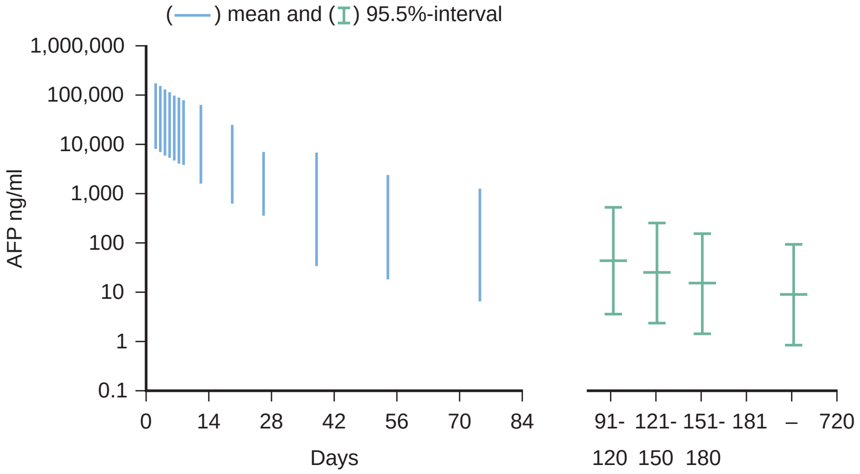

Figure 63-6 Serum AFP values in term babies, mean *(–)* and 95.5% interval *(I)*. *(From Blohm ME, Vesterling-Horner D, Calaminus G, Gobel U: Alpha 1-fetoprotein [AFP] reference values in infants up to 2 years of age.* Pediatr Hematol Oncol *15:135–142, 1998.)*

stain positive for AFP, and serum AFP is commonly elevated.[211]

Ovarian Yolk Sac Tumor

YST of the ovary is a clinically aggressive tumor that often presents at advanced stages with metastasis to lymph nodes or peritoneal structures. The tumors are rarely bilateral.[118,196,212,213] The median age at diagnosis is 18 to 19 years.[61,214-216] In a series of 26 pediatric patients, reticular type was the most common histology identified.[196]

SEMINOMA AND DYSGERMINOMA

Histopathology of Seminoma and Dysgerminoma

Seminomas are a class of GCTs in which the tumor cells resemble primitive, undifferentiated germ cells, both in morphology and in expression of pluripotency genes such as *OCT3/4, NANOG,* and *STELLAR/DPPA3*.[28,30,91,217-219] These tumor are referred to as *germinomas* when arising in extragonadal locations (such as the pineal gland, the mediastinum, or the retroperitoneum), *dysgerminomas* when arising in the ovary, and *seminomas* when arising in the testis. The histology of seminoma is identical regardless of the site in which the tumor occurs. Grossly, these are rounded, nodular tumors, separated into lobules by fibrous bands. Microscopically, seminomas are characterized by a monotonous proliferation of large, uniform cells with large central nuclei and prominent nucleoli (Fig. 63-7). The cytoplasm is clear or granular and often PAS-positive because of high glycogen content. A lymphocytic infiltrate is a typical feature of seminomas.

Seminoma

Seminoma is extremely rare in children. In the postpubertal testis, seminoma can occur in pure form or as a component of mixed GCT.[69,143,220] The peak age of onset of seminoma is 34 to 45 years, slightly later than that of nonseminomatous tumors.[69,221] Several distinct variants of seminoma have been recognized. Up to 7% of classic seminomas contain syncytiotrophoblastic giant cells, and almost 25% of seminomas contain foci that stain positive for β-human chorionic gonadotropin (HCG).[222-225] These tumors may be accompanied by an elevation in serum β-HCG; however, the presence of syncytiotrophoblasts or elevated β-HCG does not worsen the prognosis.[226-228] Marked elevations of β-HCG or persistently elevated β-HCG after orchiectomy may indicate the presence of choriocarcinoma.[229] *Anaplastic* or *atypical seminoma* is the designation used for seminomas displaying increased mitotic activity, nuclear pleomorphism, and sparse lymphocytic infiltrate on histologic examination.[230-233] Whether these aggressive features portend a worse prognosis or a higher likelihood of metastasis remains controversial. Whereas some studies have suggested that anaplastic seminomas are clinically more aggressive tumors,[234,235] others have found no evidence of a worse prognosis when these features are present.[226,230,236]

Dysgerminoma

Dysgerminoma is the most common MOGCT of children and adolescents, and makes up one third of

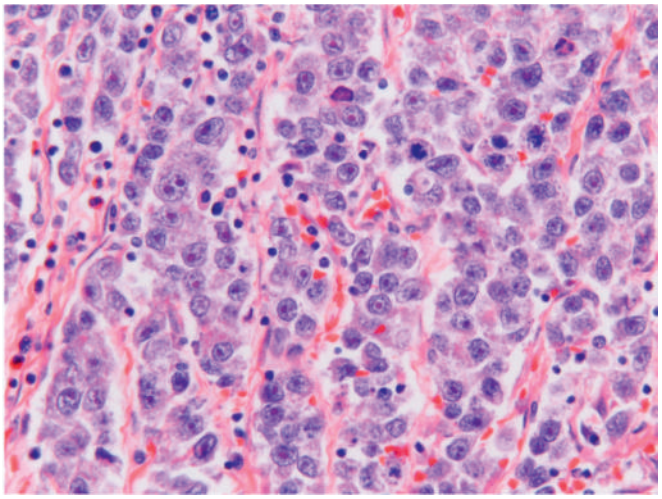

Figure 63-7 Dysgerminoma. Germinomas consist of sheets of large, uniform cells with clear or granular cytoplasm, large central nuclei and prominent nucleoli. A lymphocytic infiltrate is a typical feature of germinomas. The histologies of ovarian dysgerminoma, testicular seminoma, and extragonadal germinoma are identical.

MOGCTs.[237-239] Pathologically, dysgerminoma is the ovarian counterpart of the seminoma of the testis and the germinoma of extragonadal sites. Unlike seminomas of the testis, which are rare in the prepubertal period, dysgerminomas can occur at any age, though the peak incidence is age 15 to 19 years.[239-242] Also unlike seminomas, which develop from IGCNU, dysgerminomas do not appear to arise from a precursor cell.[162] Dysgerminomas stain positively for *OCT4* on immunohistochemistry, which can be useful for distinguishing these tumors from nondysgerminomas.[243,244] As with seminomas, the majority of dysgerminomas also stain positive for *c-KIT.*[245]

EMBRYONAL CARCINOMA

Histopathology of Embryonal Carcinoma

Embryonal carcinoma is very rare in infants but can occur in prepubertal females and adults of both sexes. Embryonal carcinomas commonly have areas of hemorrhage and necrosis and can be locally invasive into the epididymis and spermatic cord in males.[69,162] At the microscopic level, the tumors consist of large, epithelial-appearing cells that resemble the early embryonic cells of the inner cell mass (Fig. 63-8). The tumor cells may grow in solid, papillary, and reticular patterns, forming many clefts and glandlike structures. The tumors are typically cytokeratin and CD30-positive, but negative for epithelial membrane antigen (EMA), carcinoembryonic antigen, and vimentin.[162,246] Syncytiotrophoblast cells, when present in the tumor, can produce β-HCG and cause precocious pseudopuberty in premenarchal girls or vaginal bleeding in older women.[194]

Testicular Embryonal Carcinoma in Adolescents and Adults

Embryonal carcinoma is the most common pure nonseminomatous TGCT in adults, representing about 2% to 10% of cases in this age group. Additionally, 80% of mixed malignant TGCTs contain embryonal carcinoma as one component.[247,248]

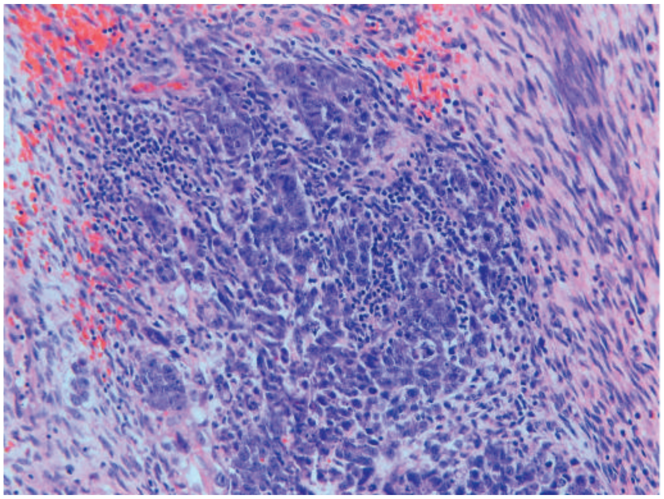

Figure 63-8 Embryonal carcinoma. Embryonal carcinomas consist of large, irregular epithelial-like cells with indistinct borders. The designation *embryonal carcinoma* derives from the resemblance of the tumor cells to the early embryonic cells of the inner cell mass.

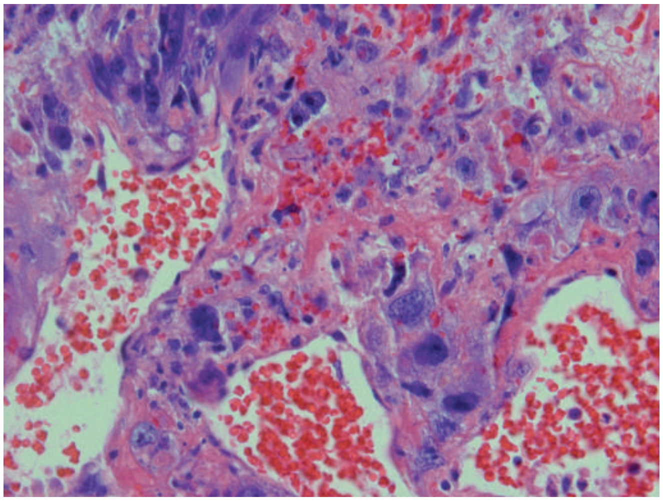

Figure 63-9 Choriocarcinoma. Choriocarcinomas are characterized by a mixture of syncytiotrophoblastic, cytotrophoblastic, and intermediate trophoblastic cells, with multiple areas of hemorrhage.

Ovarian Embryonal Carcinoma

Embryonal carcinoma occurs in the ovary less commonly than in the testis, accounting for 4% of malignant ovarian tumors.[194,196] The median age at diagnosis is 14 years, somewhat younger than ovarian YST. Ovarian embryonal carcinoma is more often associated with β-HCG production and with hormonal manifestations such as precocious puberty, amenorrhea, and hirsutism.[194] Owing to the totipotent nature of embryonal carcinoma cells, differentiation into various histologies may be seen including teratomas and syncytiotrophoblastic giant cells resembling choriocarcinoma. Polyembryoma is a rare tumor in which appear multiple embryoid bodies resembling presomite stage embryos. Polyembryoma is considered by some to be an organoid variant of embryonal carcinoma,[162] though others describe it as one component of mixed GCTs.[249,250]

CHORIOCARCINOMA

Choriocarcinoma is a rare tumor composed of cytotrophoblast, syncytiotrophoblast, and extravillous trophoblast. The tumor can cause anemia and bleeding symptoms, as well as pseudoprecocious puberty because of expression of β-HCG by the tumor cells.[118] Choriocarcinomas are usually large tumors with prominent foci of hemorrhage. The histopathology of choriocarcinoma is a mixture of syncytiotrophoblastic, cytotrophoblastic, and intermediate trophoblastic cells, often mixed in random fashion surrounding areas of hemorrhage and necrosis (Fig. 63-9).[69] Vascular invasion is a common feature of choriocarcinomas.

Testicular Choriocarcinoma in Adolescents and Adults

Choriocarcinoma, like YST, is rare in pure form but occurs in approximately 8% of mixed TGCTs in adults.[247,251]

Ovarian Choriocarcinoma

Primary (nongestational) choriocarcinoma occurs rarely as a pure tumor and more often as a component of mixed ovarian GCT, usually in association with teratoma.[238] Choriocarcinoma in infants may arise as a primary tumor in the lung, liver, brain, kidney, or other location.[118,252,253] Treatment of infantile choriocarcinoma is a medical emergency (see "Infantile Choriocarcinoma: A Rare but Rapidly Fatal Condition if Not Recognized.") Gestational choriocarcinoma arises in the placenta and may metastasize widely in the mother; case reports describe metastasis of gestational choriocarcinoma to the infant.[254] In patients in the reproductive years, deoxyribonucleic acid (DNA) analysis to detect the presence of paternal sequences can be helpful in determining the placental origin of gestational choriocarcinoma.[255,256]

MIXED OVARIAN GERM CELL TUMOR

Mixed ovarian GCTs are composed of two or more of the malignant germ cell histologic subtypes. These tumors comprise 8% of malignant GCTs of the ovary in children and adolescents and 20% of ovarian malignant GCTs overall.[61,257,258] Mixed GCTs thus represent only about 1% of all ovarian GCTs in contrast to the postpubertal testis, in which one third of GCTs are of the mixed type.[63,69,143] Dysgerminoma, YST, and teratoma are the most common germ cell components, with embryonal carcinoma and choriocarcinoma more rarely present.[63,216]

Pathology of Mixed Germ Cell-Sex Cord Tumors

Gonadoblastoma

Gonadoblastomas contain mixtures of two cell types: large cells resembling primitive germ cells and smaller cells, similar to immature Sertoli and granulosa cells (Fig. 63-10). It occurs most exclusively in cases of mixed gonadal dysgenesis with ambiguous genitalia, or 45,X Turner syndrome with Y chromosome material.[64,65,67,110] Gonadoblastoma can occur as single or multiple nodules; foci of calcification are a characteristic finding.[118] Microscopically, nests of germ cells within basement membrane material are surrounded by supportive cells (i.e., Sertoli-granulosa cells). The stroma may have elements resembling Leydig or luteinlike cells.[259] The presence of gonadoblastoma substantially increases the risk that a malignant GCT will develop in a dysgenetic gonad. From several studies, the average incidence of GCTs in gonadal biopsy specimens from patients with mixed gonadal dysgenesis is 12%.[66] Gonadoblastoma gives rise most often to dysgerminoma, and less commonly to embryonal carcinoma, teratoma, YST, and choriocarcinoma. The germ cells in dysgenetic gonads abnormally retain their embryonic characteristics, as demonstrated by their marker expression profile, including *OCT3/4* and *TSPY*. These cells give rise to gonadoblastoma in areas of undifferentiated gonadal tissue within the dysgenetic gonad, whereas IGCNU arises in regions with testicular differentiation.[*] Thus just as IGCNU is the precursor lesion for invasive TGCTs, gonadoblastoma can be considered a precursor lesion to the invasive GCTs of dysgenetic gonads.

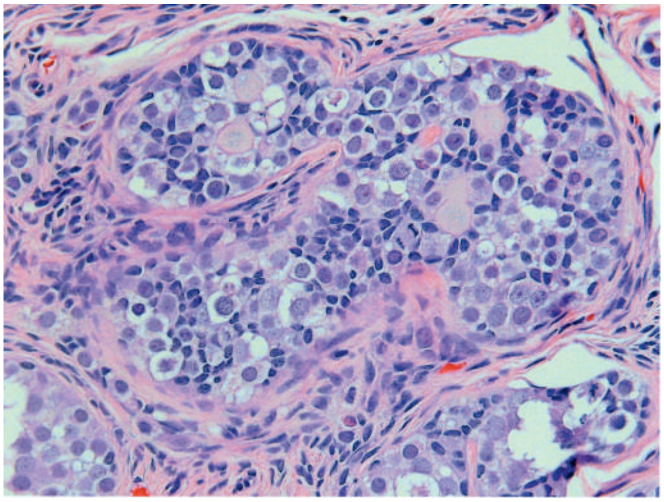

Figure 63-10 Gonadoblastoma. Gonadoblastomas are mixed germ cell-stromal tumors consisting of nests of primitive germ cells surrounded by immature-appearing Sertoli and Leydig cells.

SUMMARY OF PATHOLOGY

The five major histologic subtypes of GCTs are teratoma, YST, germinoma, embryonal carcinoma, and choriocarcinoma. In infants and children, teratoma and YST are the most common GCTs. YSTs occurring at any age are malignant tumors. Teratomas are benign in the prepubertal testis; in the postpubertal testis teratomas occur as one component of nonseminomatous GCTs and are uniformly malignant. Most ovarian teratomas are benign; however, ovarian teratomas with a significant immature component are considered malignant. Germinomas in the ovary are known as dysgerminomas and may occur in children and adults. The testicular counterpart is known as seminoma and occurs exclusively in the postpubertal setting. Extragonadal germinomas can occur in both sexes, typically in the midline of the retroperitoneum or mediastinum or in the pineal gland. The remaining tumor types (embryonal carcinoma and choriocarcinoma) are very rare in children but can occur in the testis or the ovary in adolescents and adults, either as pure tumors or as one component of a mixed GCT.

EPIDEMIOLOGY OF PEDIATRIC GERM CELL TUMORS

Incidence

Pediatric GCTs account for only a small proportion of all cancer diagnosed in children under age 20, but incidence fluctuates dramatically with age. Teratomas, which are benign, are the most common neoplasm of the newborn. However, there are malignant forms of GCT that arise in early childhood between the ages of 0 and 4 years, particularly extragonadal GCT in girls and TGCT in boys.[260]

---

[*] References 21, 26, 29, 30, 66, 110.

During adolescence, rates of GCT rise substantially for both males and females. Whereas in children younger than 15 years old, GCTs represent only 3.5% of all cancer diagnoses, during adolescence between ages 15 and 19 years, GCTs represent 16% of the total cancer burden. The incidence of testicular GCTs continues to rise throughout young adulthood, peaking in the third decade, and are the most common malignancy in men between the ages of 15 and 34 years of age.[261] Approximately 8300 cases of testicular cancer are diagnosed among adult males annually.

Extrapolating data from the Surveillance, Epidemiology, and End Results (SEER) cancer registry of childhood cancer collected between 1976 and 2006, it is estimated that in the United States, approximately 850 children and adolescents under the age of 20 are diagnosed with a gonadal or extragonadal malignant GCT each year (see Tables 63-1 and 63-2).[260] Incidence of GCT in childhood has a bimodal distribution; there is a peak in diagnosis at birth and up to age 4, and then a second peak after the onset of puberty. Histology varies dramatically with age. YST is the predominant histology in newborns and younger children, whereas tumors that arise in the peripubertal period contain a wider range of histologies, including YST, embryonal carcinoma, and choriocarcinoma, as well as germinomatous tumors (testicular seminoma and ovarian dysgerminoma).

The site of GCT varies by gender. Under age 10 years, the overall rates are similar between boys and girls, but the extragonadal site is much more common in girls than boys. Over age 10 years, incidence increases in both males and females, but the magnitude differs. Rate increases sixfold in boys but only 2.5 fold in girls. Site, however, is primarily gonadal in both sexes after puberty.

Incidence rates vary dramatically by race as well. Nonwhite boys have higher rates than white boys under age 10, but over age 10, African-American men have much lower rates than white males. In contrast, the rates of GCT are higher among African-American women at all ages. These striking differences in rates of diagnosis by race persist into adulthood; adult African-American males also have a very low likelihood of being diagnosed with testicular cancer.[262]

Incidence not only varies by race and ethnicity, but the overall incidence of GCT has been steadily increasing over the last several decades. Among pediatric patients, incidence rates between 1975 and 2006 increased among boys ages 10 to 19 years (annual percentage change, 1.2; 95% confidence interval [CI], 0.4 to 2.1) and among girls ages birth to 9 years (annual percentage change, 1.9; 95% CI, 0.3 to 2.5). In England and Wales from 1962 to 1990, investigators examined trends in cancer registry data for testicular cancer in males younger than 15 years of age and reported that on average incidence increased 1.3% per annum over the interval.[263] German investigators also report an increase in the incidence of pediatric GCTs over the last several decades.[264,265]

An increase in testicular cancer has also been noted in adult males in many of the countries of the developed world since at least 1940. In the most recent analysis of U.S. data, the incidence of testicular GCTs in adult men rose 44% between 1973 and 1998, with a more pronounced rise in seminoma (64%) than in nonseminoma (24%).[266] In a study of 22 European countries, incidence was noted to be increasing between 1% (Norway) to 6% per year (Spain and Slovenia).[267] The fact that similar trends in incidence have been observed in both young children and adults strengthen the hypothesis that it is exposures that occur either prenatally or in

early childhood that are responsible for this increase in incidence.

Possible Environmental Etiologies

Given the worldwide increase in testicular cancer of almost 100% in the last 3 decades, and the concomitant rise in pediatric GCTs, there has been significant interest in identifying potential environmental exposures that could be implicated. The parallel rise among both children and young adults has pointed to early life exposures as likely being related to development of GCTs.

One of the primary hypotheses has been that induction of GCTs occurs in the setting of prenatal exposure to high levels of maternal estrogens that could affect gonadal development.[268] Several lines of evidence suggest this is a plausible hypothesis. When diethylstilbestrol (DES) is administered to pregnant mice, it causes maldescent of the testes and testicular hypoplasia. Male offspring of women who took DES during pregnancy have higher rates of cryptorchidism, a known risk factor for TGCT in humans. Maternal use of DES has also been directly associated with increased risk of testicular cancer in some but not all studies.[269]

The fetus is also exposed to high levels of endogenous maternal estrogens during pregnancy (versus exogenous sources such as DES or oral contraceptives). Several conditions of pregnancy are known to be associated with higher levels of serum estrogens and have also been linked to increased risk of GCT, including hyperemesis gravidum and preeclampsia. Testicular cancer is more common among first-born males and twins, especially dizygotic twins, and again, both conditions of pregnancy are known to be associated with higher levels of circulating estrogens.[268,270-273] Increased birthweight, which has been associated with higher risk of testicular cancer, is also associated with higher estradiol and estriol levels in both the first and third trimesters of pregnancy.[274] Maternal weight gain is a predictor of higher birthweight and is also associated with higher insulin levels, leading to lower sex hormone–binding globulin levels, which thereby increases levels of bioavailable estrogens.

Furthering the hypothesis of the importance of early life exposures playing a role in testicular carcinogenesis, it has been noted that men born during World War II in Norway, Sweden, and Denmark have a decreased risk of testicular cancer compared with men born before or after the war. Lack of maternal weight gain during wartime may explain in part this temporal association. Rationing during WWII in Norway resulted in a 15% to 20% energy restriction and a resultant decrease in maternal weight in the period from 1941 to 1945.[275] Height, determined in part by childhood nutrition, has been found to be strongly associated with risk of testicular cancer in two case-control studies.[276,277]

Because GCTs are rare in children, the number of case-control studies conducted among children has been quite limited. The Children's Cancer Group (CCG) conducted an epidemiologic study that included all children with cancer registered for treatment with CCG between 1982 and 1989.[278] Parents were asked to complete a 22-page self-administered questionnaire. Approximately 50% of those with children who had eligible cancer cases completed the questionnaire; controls were obtained through a random-digit–dialing procedure. Among all the cases, there were 105 cases of children younger 15 years of age with a malignant GCT and 639 controls. In this study, several factors were associated with risk of GCT. Birthweight of more than 4000 g was related to 2.4-fold increase in risk (CI, 1.0 to 5.8) compared with a birthweight of less than 3000 g after adjustment for gestational age. Pregnancy conditions such as nausea and vomiting or hypertension or eclampsia were not associated with risk. An inverse association between maternal smoking and risk was noted; among mothers who smoked more than 15 cigarettes per day, risk of GCT was reduced by 70%. Among mothers who ever reported being exposed to chemicals or solvents or to plastic and resin fumes, an increased risk was observed (odds ratio [OR] 4.6; CI, 1.9 to 11.3); (OR 12.0; CI, 1.9 to 75).

A more in-depth follow-up study that specifically focused on GCTs in children was conducted under the aegis of the Children's Oncology Group (COG).[279] The study included 278 cases and 423 controls identified through random-digit dialing. Subjects completed a self-administered questionnaire, a telephone interview, and a medical record review of the maternal records before and during the index pregnancy. The study did not confirm a relationship between maternal exposure to exogenous hormones (either DES or oral contraceptives) and risk of pediatric germ tumor. None of the pregnancy-related conditions including birthweight, hyperemesis, preeclampsia, pregnancy-induced hypertension, or maternal weight gain that can alter circulating levels of endogenous estrogen were related to risk.[279] The study also failed to replicate the finding from the prior case-control study in CCG that showed a relationship between maternal smoking and decreased risk of GCT[280]; neither environmental or occupational exposure to pesticides and other chemicals increased risk of GCT in offspring.[281]

Predisposing Syndromes

Cryptorchidism and Testicular Cancer

Many studies have shown a definitive relationship between cryptorchidism and testicular cancer with relative risks that range from 2.1 to 17.6.[282] Of note, cryptorchidism is three to four times more common in white males than African-American males, which mirrors the difference in incidence by race. The etiology of the relationship between cryptorchidism and testicular cancer remains unclear. It has been suggested that exposure of the testis to higher temperatures in the abdomen as compared to in the scrotum in some way promotes cancer growth. In this case, orchiopexy should minimize risk, especially if it is done before the hormonal stimulation and proliferation of puberty. Others have suggested that the etiology of the undescended testicle and the cancer is the same, and in this case, orchiopexy should not significantly decrease risk. It has been observed that there is an increased risk of testicular cancer in the descended contralateral testicle, which supports this hypothesis for a common etiology. In a case-control study from Kaiser-Permanente of 183 patients with testicular cancer matched to 551 controls, there were 20 men who had had a cryptorchid testes.[283] Interesting, if orchiopexy had been performed successfully by age 11, there was no increase in risk of testicular cancer. However, among men whose cryptorchid testis was not treated until after their eleventh birthday, who had a failed orchiopexy, or who had never had treatment, the odds of testicular cancer were increased 32 fold. Although the study was limited by small numbers, it would suggest that orchiopexy in early childhood before puberty may obviate the risk of subsequent testicular cancer. In the case in which an abdominal testes is discovered after the onset of puberty, an orchiectomy may be the most prudent procedure.

Turners Syndrome and Gonadoblastoma

Turner syndrome, the most common sex-chromosome abnormality in girls (1:2000 live births), is caused by partial or total loss of an X chromosome, resulting in a 45,XO karyotype. Most girls with Turner syndrome have short stature and many have primary amenorrhea. Approximately two thirds of girls have only the remnant of an ovary or “streak gonad.” In these dysgenetic and often nonfunctional ovaries, there is a high risk of developing a gonadoblastoma, particularly in girls who also retain a portion of the Y chromosome. Gonadoblastoma is itself a benign lesion, but some of these tumors undergo malignant degeneration, and therefore gonadectomy is usually recommended, although this recommendation has become more controversial. In a Danish study that examined 114 girls with Turner syndrome, presence of the Y chromosome was documented in 13 girls (12%).[284] In the 10 girls with Y-chromosome material who subsequently underwent gonadectomy, gonadoblastoma was present in only one specimen. Therefore the authors suggest that close follow-up examination by ultrasound may be sufficient for monitoring rather than routine gonadectomy but urged that more prospective data is necessary.

Klinefelter Syndrome

Klinefelter syndrome, a condition present in between 1:500 and 1:1000 males, is caused by an extra X chromosome resulting in the 47, XXY karyotype. Men with Klinefelter syndrome have abnormal testicular development and are usually infertile. Men with Klinefelter syndrome also have a substantially increased risk of developing GCTs, particularly mediastinal GCTs, beginning in early adolescence.[285]

Androgen Insensitivity Syndromes

Mutations either in the androgen receptor itself or its downstream effectors results in phenotypic females with an XY karyotype. The prevalence of this disorder is estimated to be approximately 1:20,000 females. Oftentimes, these patients do not come to medical attention until they undergo evaluation of primary amenorrhea. Patients with complete androgen insensitivity have little to no axillary or pubic hair, no uterus, and serum testosterone levels of a male. Testes are abdominal or inguinal but can also present on rare occasions as labial masses. These cryptorchid testes are at high risk for development of gonadoblastoma and/or more malignant GCTs and gonadectomy is advised.

MOLECULAR BIOLOGY OF GERM CELL TUMORS

Analysis of the GCT genome and transcriptome has begun to yield insight into the pathogenesis of these tumors in recent years. Genome-wide association studies (GWAS) comparing GCT cases with unaffected controls have identified a number of loci linked to GCT susceptibility. Several different types of analyses, described in the following sections, lend support to the idea that prepubertal and postpubertal GCTs arise from different molecular mechanisms. In the coming years, identification of specific gene expression signatures, mutations, copy number aberrations, and other abnormalities in different subclasses of GCTs will undoubtedly help refine risk stratification in newly diagnosed patients, as well as provide new targets for novel therapies, especially in chemotherapy-resistant disease.

The GCT Transcriptome

In the last decade studies have begun to illuminate the messenger ribonucleic acid (mRNA) expression pattern of TGCTs in adult men.[218,286-290] These analyses have revealed gene signatures distinguishing GCTs from other types of malignancies and further identified differences in gene expression among different histologic subtypes of GCTs. A major unresolved question of whether pediatric GCTs exhibited the same gene expression patterns was addressed by Palmer, Coleman, and co-workers in an investigation of the pediatric GCT transcriptome, the largest such study to date.[291] This study demonstrated striking differences in the gene expression repertoire of malignant YSTs compared to seminomas, with the former enriched for genes associated with the self-renewing or pluripotent phenotype and the latter enriched for genes associated with differentiation and proliferation. In addition, Palmer et al compared gene expression in childhood GCTs with that in adult TGCT, as described in a study by Korkola et al.[292] The analysis of Palmer and colleagues showed clear differences between the transcriptional profile of pediatric and adult GCTs, even within the same histologic subtype (Fig. 63-11, *A* and *B*).

A key additional question is whether particular gene expression patterns are associated with clinical outcome in GCTs, a point addressed by some studies of adult TGCT.[287,293] A study by Korkola and co-workers identified and validated a prognostic mRNA gene expression signature that defined 5-year overall survival in both a training and validation cohort of nonseminomatous TGCTs.[293] Further work will be required to translate this finding into a robust, clinically useful prediction tool.

Noncoding RNAs

Micro RNAs (miRs) are short, 21-nucleotide, noncoding RNAs that have major roles in regulating gene expression and are often misexpressed in cancer.[294] A seminal study in 2006 identified miR-372 and miR-373 as oncogenes in TGCTs—one of the first demonstrations that miRs play a role in human cancer.[295] In childhood GCTs, Palmer and co-workers demonstrated that relative to normal gonadal tissue, MGCTs overexpress miRs from the miR-371~373 and miR-302 clusters, regardless of histologic subtype, patient age, or gonadal vs. extragonadal origin.[296] This study also demonstrated that expression of these miRs causes specific downregulation of their target miRs in GCTs. In a subsequent study, Murray et al. further defined miRs with differential expression that distinguished YSTs from germinomatous GCTs and identified a core set of transcription factors that may be regulated by these miRNAs and contribute to the specific cellular phenotypes of different subtypes of GCT.[297]

Micro RNAs have been shown to be shed from tumor cells into the circulation.[298] The translational significance of the finding that miR-371~373 and miR-302 family members are universally overexpressed in GCTs became clear with the demonstration that these same miRs were present at elevated levels in the serum of a child with YST at diagnosis and fell in parallel with declining AFP levels during treatment.[299] Further studies have confirmed that serum levels of these miRs are increased in patients with GCT at diagnosis, regardless of age group, tumor histology, or location (Fig. 63-12).[300,301] This is a particularly important finding, since many patients with GCT do not manifest elevation of serum tumor markers such as AFP, HCG, or lactate dehydrogenase (LDH).[302] Serum miRs may thus represent sensitive and specific new tumor markers for MGCTs.

Chromosomal Constitution and Copy Number Aberrations

The analysis of tumor karyotypes and genomic copy number aberrations (CNAs) in GCTs provides some of the most important evidence for distinct pathogenic mechanisms of GCT in children compared with adolescents and adults.[60,154,202,303-305] In addition, the gain or loss

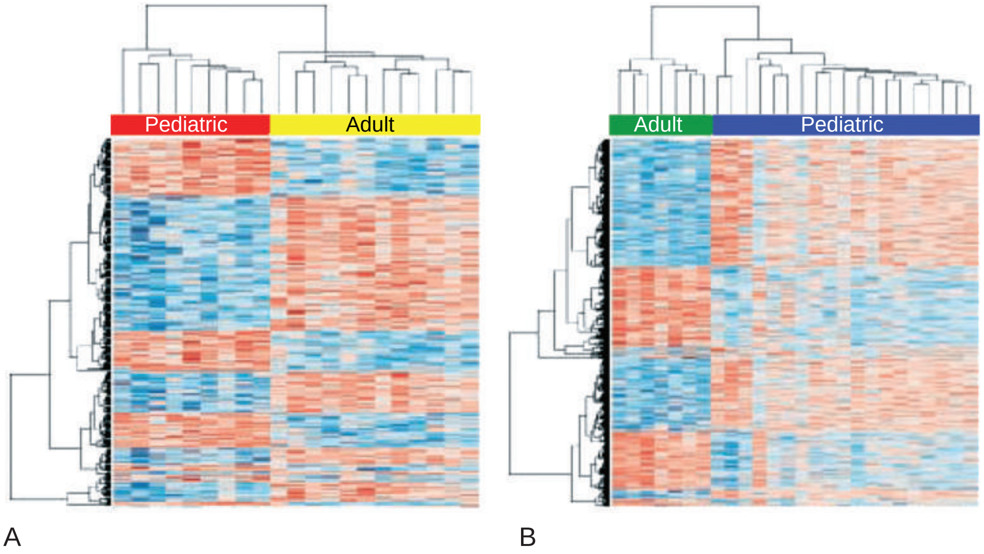

Figure 63-11 Pediatric and adult germ cell tumors (GCTs) display different gene expression patterns. Heat maps comparing the transcriptomes of 27 pediatric GCTs with that of pure histologic diagnosis adult TGCTs. **A**, Seminomas. **B**, YSTs. *Red* represents relative overexpression and blue represents underexpression. *(Modified from Palmer RD, et al: Pediatric malignant GCTs show characteristic transcriptome profiles.* Cancer Res *68:4239–4247, 2008.)*

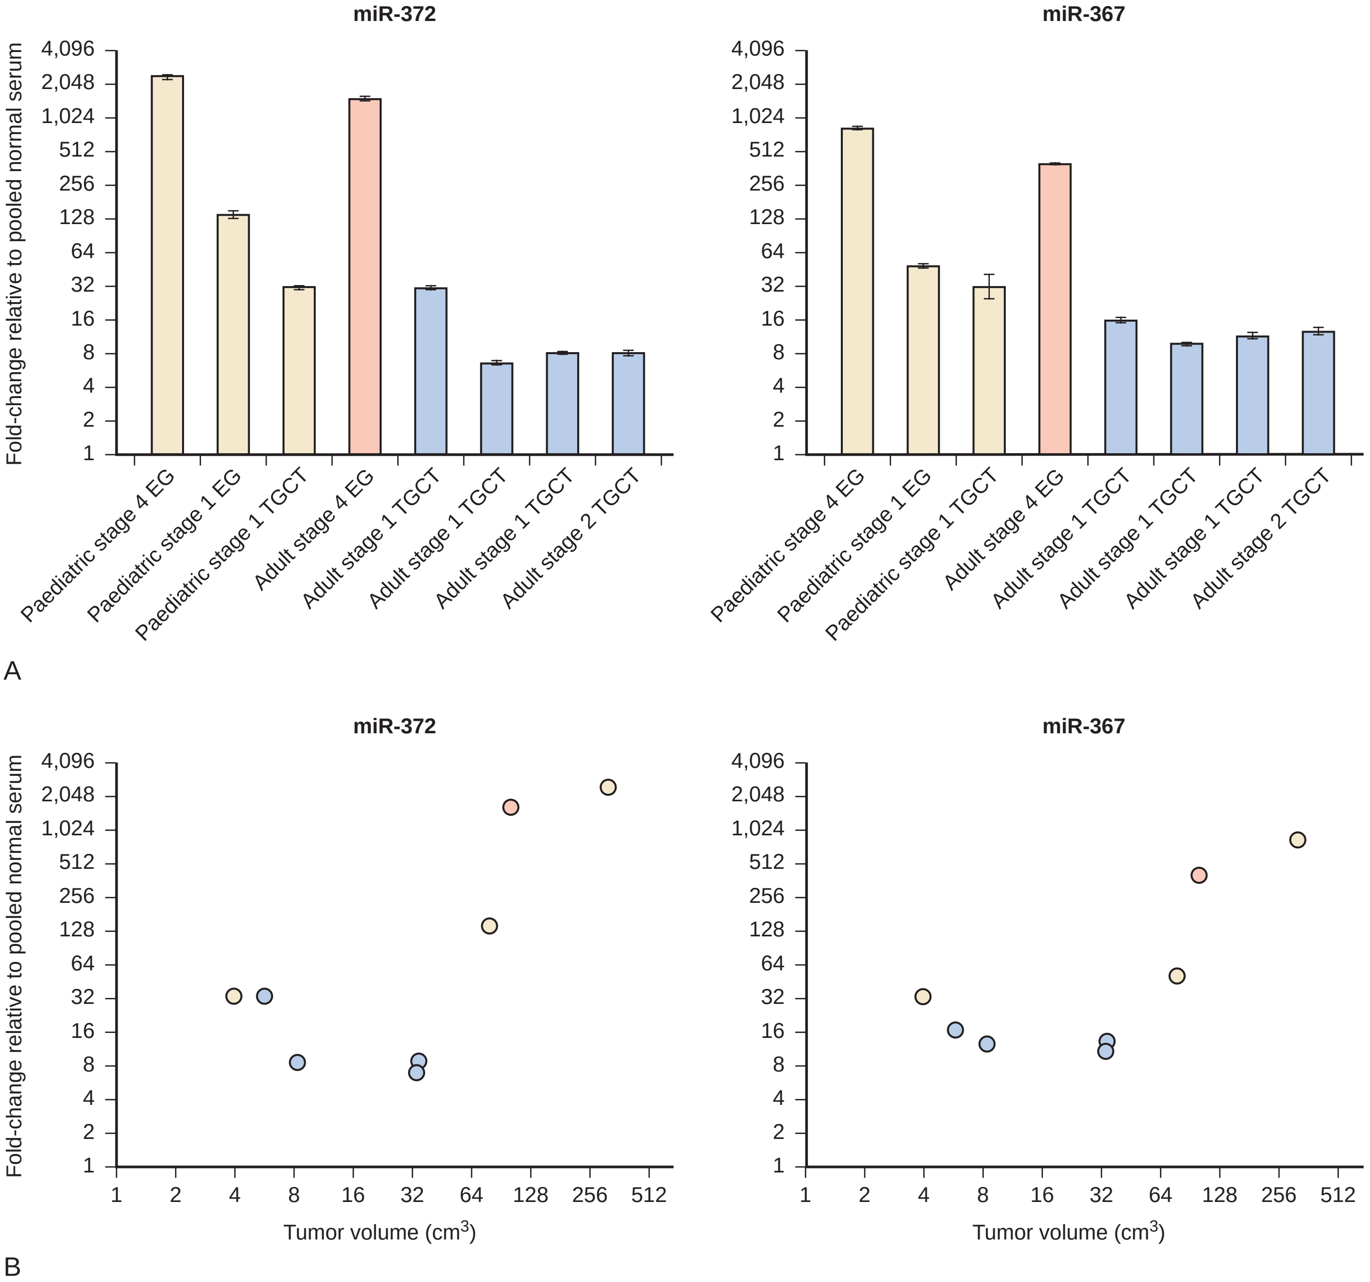

Figure 63-12 MiRs as serum biomarkers of malignant germ cell tumors (GCTs). **A**, Relative levels of miR-372 *(left)* and miR-367 *(right)* in the serum of patients with GCTs at diagnosis, compared with levels in control serums. MiR-372 and miR-367 are elevated in all patients regardless of age, site or tumor histology. **B**, Serum expression of miR-372 and miR-367 at diagnosis correlates to volume of the primary tumor. *(Modified from Murray MJ, Coleman N: Testicular cancer: a new generation of biomarkers for malignant germ cell tumours.* Nat Rev Urol *9:298–300, 2012.)*

of specific chromosomal regions may provide important clues as to the molecular mechanisms of germ-cell tumorigenesis.[1,69,94]
